Water flows and water distribution are closely coupled with gas fluxes and gas exchange with the atmosphere. Soil pores are the conduits of gases, and their characteristics, specifically size distribution and shape, are important. Large empty pores with low tortuosity that directly open into the atmosphere are oxygen rich and supply oxygen to the surrounding soil matrix. Gas flow through tortuous pore space is slower. Gas diffusion in water-filled pore space is by orders of magnitude slower than in the air. Joint influences of pore distribution through the soil matrix and water distribution within them greatly amplify the heterogeneity of the soil micro-environments in terms of oxygen levels. Some of the fine pore regions, removed from large atmosphere-connected pores, might remain low on oxygen during most of the year, others, like preferential flow pathways, might stay mostly aerobic, except for brief periods of saturation, yet still others might be changing from oxic to anoxic conditions often.

It should be noted that even in air-filled pores the humidity of the soil atmosphere is typically very high (~98%), enabling survival and functioning of many invertebrate and microbial organisms. Availability of fully- to partially-air filled pores is an important condition for fungi growth and for dispersion of fungi and its colonization of the soil habitat. Many soil invertebrates are sensitive to temperature and drought, thus abiotic habitat characteristics can be more important than trophic resources in defining suitability of particular soil habitat.

pH

Soil pH, the concentration of H^+ ions, can directly and indirectly affect the functioning of many soil organisms. The indirect influence can be manifested through the role of pH in governing availability of nutrients to soil organisms, notably P and Fe. Among the indirect influences are modulations of the activity of extracellular enzymes (EE). While EE may differ in terms of specifics of their optimal pH levels, any deviations from the optimal pH will reduce the enzyme activity and thus the returns on investment for those who produced it.

Among the many mechanisms driving soil pH are the following:

- 1) Dissolution of atmospheric CO_2 in the water and subsequently generated carbonic acid.
- 2) Dissolution of SO_2 and N oxides in the water generating sulfuric and nitric acids.
- 3) Microbial activities such as nitrification, redox reactions, and organic matter decomposition, where the latter is enhanced by agricultural activities, particularly plowing.
- 4) Plant activities; plants continuously release H^+ or OH^- to balance uptake of cations and anions at the root surface, along with organic acids and other exudates. Root respiration, also increases the concentration of CO_2 in soil with subsequent carbonic acid dissolution, as well as alters pH via redox-coupled reactions.

Anthropogenic influences play a substantial role in modulating soil pH. In agricultural soils NH_4^+ and NO_3^- additions as chemical fertilizers decrease pH, whereas lime and organic amendments, e.g., manure, increase it. Sulfur-rich acid rains enhance soil acidification worldwide. Yet, natural sources, such as sulfide enriched parent materials (e.g., pyrite), emissions of acid-generating gases during volcanic eruptions, or their production during thunderstorms, also play a role.

Most of the world's soils are acid with a pH range of 3.0–5.0, including soils of tropical and of boreal regions. It is the soils of grasslands and forests in temperate regions that tend to have neutral, 6.0–7.0, pH, whereas those of arid regions have neutral-to-alkaline pH of 7.0–8.0. However, in many soils, pH varies with depth, e.g., pH can be 3.5 in the A-horizon while measuring 5.0 in a C-horizon of the same soil profile. Moreover, the microscale patterns in spatial distribution of pH within the soil matrix can be extremely spatially and temporally variable. For example, pH can easily fluctuate within a 1–2 unit range across just a few millimeters

Fig. 3 An example of variability in distribution of pH in the rhizosphere and bulk soil (Ma et al., 2021). From Ma X, Liu Y, Shen W, and Kuzyakov Y (2021) Phosphatase activity and acidification in lupine and maize rhizosphere depend on phosphorus availability and root properties: Coupling zymography with planar optodes. *Applied Soil Ecology* 167: 104029.

of the soil matrix, driven by microscale variations in the factors listed above. It is notable that rhizosphere soil often has pH that is 1–2 units less than that of the bulk soil, with the contrast especially large when plants are experiencing P or Fe deficiencies (Fig. 3). Local nitrification spots in well-aerated pores can increase acidity locally, whereas the absence of oxygen and subsequent denitrification can reduce it. High spatial variability at the microscale is often coupled with high temporal variability, and the local pH changes in the rhizosphere can occur within the timeframe of a few hours. The microbial and micro-faunal organisms that lack the mobility for them to escape the unfavorable change must thus be able to adjust rapidly to pH fluctuations. Switching from acid to alkaline phosphatase production as a function of soil pH is an example of such acquired adjustment capabilities.

Biotic conditions

Most of the carbon in soil originates from atmospheric CO₂, which is photo-assimilated and placed belowground by plants. The rest of the nutrients, N, P, K, etc., originate primarily from soil minerals, where weathering is instrumental in their availability to plants and soil organisms. For example, the manganese (Mn), needed by plants for their photosynthetic activity, is obtained in a soluble form from weathering of primary aluminosilicate minerals and secondary minerals, often from deep within the soil profile. The Mn-rich leaves return to the soil surface with litter fall; this enriches the topsoil with soluble Mn providing it for subsequent uptake by plants, but also for use by a variety of soil organisms.

Soil heterotrophs are arguably the most abundant group of soil organisms. They get their nutrients from organic residues, with those of plant origin, either from live plants or their detritus, being the main source. Decomposition of inputs might be regarded as the key process underlying most of the activities in the soil.

The main types of plant inputs are from aboveground plant biomass (leaves and shoots), root biomass, and rhizodeposition. Chemical composition of the organic detritus is of major importance: it defines how much C is turned into the soil, quality of the added organic, thus its suitability for soil mesofauna and microorganisms, the form, quantity, and variety of nutrients added, soil pH, and other factors. Characteristics of soil organic matter influence its suitability as a trophic resource for soil inhabitants, both microorganisms and invertebrates that consume it directly. Yet, the importance of the indirect positive effects of soil organic matter accumulation on optimizing soil pH and increasing soil water holding capacity, while improving structure formation and thus oxygen supply, cannot be overstated.

Aboveground biomass contributes to soil C supply and nutrient turnover, when decomposed on the soil surface, with dissolved organic C and other decomposition products seeping into the topsoil. It also can be incorporated into the soil by animal activity, such as when earthworms drag leaves into their burrows, and further processes by fungi. In agricultural soils, tillage is a key route through which aboveground plant residues end up within the topsoil.

Roots play by far the largest role in building the soil habitat, and fine ($< 2 \text{ mm } \varnothing$) roots with their large spatial spread and fast turnover are especially important. Biomass of senescent roots is a very important source of organic inputs for soil organisms. The rhizodeposits, including root exfoliations, exudates, and other secretions (e.g., mucilage), as well as inputs of root organics into the soil via mycorrhizae, are other major contributors of organic inputs. Physical characteristics, such as root biomass, architecture, and morphology, directly define the formation of soil pore structure. The chemical composition of roots also defines their decomposability, similar to that of the aboveground biomass. Roots actively construct soil structure and soil pores, where pores are built by the direct physical impact of the roots. But the organic inputs from live and decomposing roots glue soil particles together, with subsequent wetting, drying, freezing, and thawing indirectly contributing to soil pore formation and stability.

Soil porosphere

It should be noted that all soil dwellers live within the soil pore space, either inside of the pores of their own creation, e.g., earthworms, or on pore-solid interfaces of existing soil pores, e.g., mesofauna and microorganisms. Earthworms and many other members of soil meso- and macrofauna are actively building their own living quarters within the soil creating their own habitat and acting as architects of the soil as a whole.

The special physical features of porous materials described above are relevant, both to fully developed soils and to all possible porous materials, justifying the concept of “the porosphere” (Vannier, 1987). Porosphere is defined as all solid materials with internal, i.e., porous, space, and soils is one of the most important members of that group. The characteristics of the porosphere that separate the conditions within it from any other soil environment are:

- 1) limited light access,
- 2) high CO_2 levels,
- 3) special features of its water, including water absorption on the surfaces of soil pores, water being held at negative potential, and frequent and widespread high relative humidity of the gaseous phase, and
- 4) exceptionally high micro-scale heterogeneity in spatial distribution of solid, liquid, and gaseous components exacerbated by a nearly infinite amount of completely separated or poorly connected pore spaces and particularly high volume of the small pores.

These characteristics played a major role in the evolution of not only soil microorganisms, but all members of the soil fauna. For example, high integumental permeability and resistance to high levels of CO_2 , characteristic of soil mesofauna, are responses to porosphere environment. It is argued that high humidity and water availability in the porosphere of the ancient Earth made the soil an intermediate step for movement of the organisms from the oceans and lakes. Likewise, great volumes of pore spaces inaccessible to plant roots but accessible to fungi in the soil porosphere drove the development of mycorrhizae as a more efficient way for plants to fully explore the resources of the soil matrix.

Although variations due to differences in mineralogy and organic inputs can be expected, the overall patterns in the microenvironmental conditions provided by pores of different sizes can be regarded as universal. They are based on organism and root size requirements, nutrient input patterns, and gas and water flow drivers (Fig. 4).

The large ($>500 \text{ } \mu\text{m}$ diameter) pores are of suitable size to host soil micro- to mesofauna, while very large ($>2000 \text{ } \mu\text{m}$ diameter) pores are needed for larger members of the mesofauna as well as for the macrofauna (earthworms, millipedes, etc.). Conditions within all large pores are similar in terms of almost invariably high levels of oxygen, due to ample connections with the atmosphere, but little water availability. The origin of the large pores in combination with other soil physical characteristics defines nutrient availability within them. Abiotic cracks receive nutrients only in a form of mobile organic C flowing through them during the saturation events and deposited as SOM- and clay-rich cutans formed on their walls, yet such events are infrequent, and the flows are fast. Large pores of biological origin, biopores, are highly enriched in nutrients originating from earthworm slimes and feces, root exudates, and root residues and are easily available to small fauna and microorganisms. But despite their potentially high nutrient levels, all large pores present challenges to their inhabitants in terms of water availability, since they are the first to empty of water and dry completely, and then to remain arguably the driest portion of the soil body. Moreover, the biopores of earthworm or plant

Fig. 4 Pore habitats and their key features (Kravchenko et al., 2020) specifying water and oxygen availability trends, root input contributions to pores of different size ranges, and assessments of size-wise suitability of pores to different types of inhabitants. Also highlighted are pore-size ranges contributing the most to soil C protection and biological activity. From Kravchenko AN, Guber AK, Razavi BS, Koestel J, Quigley MY, Robertson GP, and Kuzyakov Y (2020) Reply to: “Variables in the effect of land use on soil extrapore enzymatic activity and carbon stabilization” by Glenn (2020). *Nature Communications* 11.

origin as well as abiotic cracks often serve as preferential flow pathways, subject to what could be seen as micro-scale flash-floods, with a powerful impact on their inhabitants.

The medium-sized (tens to hundreds μm diameter) pores are appropriate to host the microfauna (e.g., protozoa and nematodes) as well as the smallest members of the mesofauna groups. Many microorganisms form colonies embedded in hydrated extracellular polymeric substances – medium-sized pores are big enough to accommodate such structures. Overall, the space of medium-sized pores has several advantages over that of the large pores. It provides a greater balance between oxygen availability - frequent and sizeable, and water availability - at optimal levels for longer periods of time than in the large pores. Although medium-sized pores might well suit soil organisms in terms of their physical characteristics, it is the availability of nutrients which is the necessary condition for turning such pores into optimal habitats. Among the sources of nutrients in these pores are:

- 1) fine plant roots and root hairs – the most active components of plant root systems in providing C inputs via exudates and rhizodeposits;
- 2) decomposition products leaching out of POM fragments and senescent fine roots; and
- 3) mobile organic C brought by the inflowing soil solution.

It should be noted that, compared with large pores, the flow velocities within the medium pores are slow, leaving more time and opportunities for the entrained organic C and nutrients to interact with minerals of pore wall surfaces and to become accessible to their inhabitants. Medium pores do experience sporadic anoxic conditions. This happens during soil saturation and during periods of high microbial activity when the rate of oxygen consumption exceeds that of its diffusion, the latter especially relevant for the

nutrient-rich pore spaces. The connectivity of large and medium-sized pore spaces is a major contributor to dispersion and interactions among micro- to mesofauna species, and the lack of it stimulates diversity not only of microbes but also of soil mesofauna.

Small-sized pores can be especially variable in what they offer as habitats to soil microorganisms and microfauna. Their suitability greatly depends on their relative position with respect to other elements of the soil matrix, such as large and medium pores and nutrient sources, (e.g., plant roots and POM). Whereas, overall the small pores often have low levels of oxygen and tend to stay water-saturated for the longest time, the oxygen deficiencies can be frequently alleviated if they are located nearby air-filled large and medium pores. However, the small pores deep within the soil matrix, far from any air-filled bigger pores, likely remain persistently anaerobic. The small pores in the rhizosphere are more likely to have constant inputs of C and nutrients of root origin, while the ones within the bulk (i.e., not rhizosphere or detritosphere) soil have a very limited nutrient supply. The only mechanisms through which C and nutrients can reach small pores within the bulk soil are capillary flow of soil solution and diffusion of the chemicals; both processes are slow and inefficient in providing the nutrients to the inhabitants.

The relative proportions and volumes occupied by different pore-size groups can vary greatly among soils of different types and geographies, reflecting a multitude of influences on soil formation and inherent soil characteristics, including texture, soil history, vegetation, and management. Pore space constitutes 40–60% of the total soil volume, but a sizeable (>30%) proportion of it are pores with diameters <1 µm, thus not suitable as a habitat even for the smallest of soil microorganisms. In mineral soils the volumes of small- medium- and large-sized pores can constitute 20–80, 10–40, and 5–10% of the pore space, respectively.

Special habitats: Rhizosphere and detritosphere

Due to their substantial C and nutrient availability, rhizosphere and detritus present two very special environments within the soil matrix and can be regarded as separate habitats in their own right. They also differ from the other portions of the soil matrix in terms of physical characteristics. They can be viewed as “hot-spot” habitats, existence stemming from concentrated sources of labile C that are highly variable, both spatially and temporally (Kuzakov and Blagodatskaya, 2015):

Rhizosphere

The rhizosphere possesses a number of characteristics that make it arguably an optimal soil habitat for soil microorganisms, micro-fauna and, possibly, meso-fauna. Plants provide the soil around them with organic compounds of exceptionally wide chemical diversity creating a drastic contrast between rhizosphere and bulk soil nutrient supply. Many of the compounds exuded by the roots come out in quantities that are below what would be of nutritional value to the organisms, but instead are signal molecules that recruit microbial symbionts, and indirectly influence many other microorganisms and fauna. Plants also generate fluxes of H⁺, OH⁻, cations, anions in the rhizosphere, majorly affecting its biochemistry. The rates and quantities of plant outputs and intakes are strongly affected by plant species, root age, soil texture, soil moisture content, and the pore structure encountered by the roots.

Roots tend to grow into pores somewhat bigger than themselves, preferring the pores that are relatively well interconnected and connected to the atmosphere. Often a root does not fully occupy the entirety of the pore, leaving what is known as a “root gap.” Formation of a root gap, together with high oxygen consumption by the roots themselves and by the active microbial and faunal life in the rhizosphere, leads to highly dynamic oxygen availability. When soil becomes wet, and the pores formed or modified by roots become the pathways for preferential water flow, subsequent oxygen consumption and slow gas diffusion will lead to temporal onset of anoxic conditions. Yet, upon soil drying, speeded up by the root water uptake, oxygen availability may be restored within a few hours. Moreover, roots greatly influence the water content within the rhizosphere, they either absorb it, generating water flow toward the root surface and often resulting in a smaller water content in the root vicinity, or they maintain the content somewhat above that of the bulk soil when the latter becomes dry. The magnitude and dynamic of such fluctuations greatly depend on the plant species and soil physical characteristics.

Though the area of the most active rhizosphere expands to 1–3 mm from the root, the overall sphere of root-influence can extend as far as 20 mm for fast diffusing small-molecule compounds consumed by the roots, e.g., depletion of NO₃⁻ in the root vicinity. Furthermore, the sphere of influence can be <1 mm for some of the heavy organic molecules of root exudates or extracellular enzymes. Thus, the outcome is a gradient of micro-environmental conditions expanding from the root surface into the bulk soil, rather than an abrupt rhizosphere boundary.

While we generally refer to all soil in close proximity to roots as the rhizosphere, it should be noted that specific inputs and environmental conditions vary drastically and very rapidly along the length of a growing root. What was once a micro-region receiving inputs from a root tip and promoting fast-growing bacteria, becomes a location of root hairs supporting mycorrhizal fungi, and then a place adjacent to an older root benefiting root-grazing fauna. These changes may take place within a few hours to a few days.

Detritosphere

Plant and animal residues, i.e., their detritus, and soil in their immediate vicinity, i.e., the detritosphere, form yet another unique soil habitat (Fig. 5). It resembles rhizosphere in terms of a plentiful supply of C and nutrients available to soil microorganisms and micro- and mesofauna, but has a number of differences.

Fig. 5 Detritus from straw (A) incubated within the soil for 30 days and colonized by fungi (F) and bacteria (B) in proximity ((B) and (D)) and at greater distance (C) from the residue (Gaillard et al., 1999). From Gaillard V, Chenu C, Recous S, and Richard G (1999) Carbon, nitrogen and microbial gradients induced by plant residues decomposing in soil. *European Journal of Soil Science* 50: 567–578.

The properties of the detritosphere are a function of (i) the nature of detritus itself, i.e., its origin, chemical composition and physical characteristics, (ii) the properties of the soil surrounding the detritus, i.e., soil texture and pore characteristics, and (iii) the soil moisture regime. How available is the detritus to decomposition and the quantity and quality of nutrients it can provide vary substantially, and also change with time as decomposition progresses. Whether a fragment of detritus is surrounded by the tightly adherent soil with limited gas diffusion or is in a relatively large air-filled pore will lead to contrasting conditions for the activity of heterotrophic organisms and the decomposition rates. The former case might be typical for fragments of aboveground plant biomass incorporated into the soil, while the latter for the detritus of the root origin. The decomposition products diffuse out of the decomposing residue into the surrounding soil supporting the organism within. The distance for such diffusion varies from a few tens of microns for some large organic molecules to a few millimeters for NO_3^- .

The overall soil moisture content will affect the longevity of a particular detritosphere spot through its influence on decomposition. For example, speeding it up in wet soil with good oxygen supply, or slowing it down when the conditions are too dry or too wet and anoxic. The soil moisture also affects the spatial extent of the detritosphere influence - it can be expected to be larger under wetter conditions compared to drier conditions. Yet due to their fine pore structure, tissues of many plant residues, especially at the early stages of decomposition, can act like a sponge, absorbing water from the surrounding soil. Thus, they may provide water for the decomposers even when the overall soil moisture is relatively low.

Abstract

There is insufficient food to adequately sustain the population of the world, either now or in the future. However, the food supply might be increased sustainably by employing plant-beneficial soil microorganisms in agriculture. These microorganisms have naturally facilitated plant growth and development for millions of years and can support plant growth directly or indirectly by decreasing the damage caused by phytopathogens. The beneficial microorganisms include plant growth-promoting bacteria (PGPB), mycorrhizal and endophytic fungi. PGPB may be rhizospheric, endophytic, symbiotic, or phyllospheric. Microorganisms may act as consortia to benefit plant growth including bacteria-bacteria, bacteria-mycorrhizae, and Bacteria-Trichoderma consortia.

Key points

- There is not enough food to adequately feed the population of the world.
- One way to sustainably improve food production is using plant-beneficial soil microorganisms.
- Many different soil microorganisms facilitate plant growth.
- These microorganisms use a range of mechanisms to promote plant growth, both functioning individually and working together in consortia.
- Beneficial microorganisms include plant growth-promoting bacteria, mycorrhizal fungi, and *Trichoderma* spp.
- Plant growth-promoting bacteria may be rhizospheric, endophytic, symbiotic, or phyllospheric.

- Mixtures of microorganisms that act as consortia to benefit plant growth include bacteria-bacteria, bacteria-mycorrhizal fungi, and Bacteria-Trichoderma consortia.
- Some plant growth promoting bacteria, mycorrhizal fungi and Trichoderma have already been commercialized.

PGPB	Plant Growth-Promoting Bacteria

Introduction

Need for non-chemical (natural) means of promoting plant growth because of increasing population and global climate change

The production of food on a global scale is dependent on agriculture, the main objective of which is to provide enough food for the world population. In 2020, a United Nations report on the global State of *Food Security and Nutrition* concluded that almost 690 million people suffered from hunger in 2019, which was 10 million more than in 2018 and the number had increased by slightly less than 60 million over the previous 5 years. In addition, the fraction of undernourished people was approximately 9% of the world's population, and over the last 5 years the trend in this parameter has increased, suggesting that food demand relative to food availability has increased proportionally with the world population (<http://www.fao.org/3/ca9692en/online/ca9692en.html#>).

At the same time, due to the increase in the amount of greenhouse gasses in the atmosphere the world is witnessing dramatic climate change especially with respect to temperature and rainfall patterns, creating stressful conditions for plant growth and productivity. Abiotic factors such as salinity (10%), low and high temperatures (7% and 20%, respectively), drought (9%), and other stress conditions (4%) can lead to a ~50% global loss of crop productivity. It is also true that climate change favors the propagation of pests and soil borne diseases, potentially bringing additional significant losses in global agricultural yield.

Intensive agriculture has been viewed as one solution to this problem, however, this approach is based on the use of large amounts of chemical pesticides and fertilizers to maximize plant and crop yields to keep up with the growing global food demand. However, these chemicals accumulate in soils and water, polluting ecosystems, resulting in a plethora of environmental and human health issues. At the same time, consumers have become more aware of the impact of these chemicals on their diet and health. Thus, the demand for healthy, nutritious foods is rapidly increasing in both developed and developing countries. Therefore, a significant reduction in the use of chemical inputs in agriculture is necessary, and the application of environmental sustainability principles has become an essential target shared by many farmers and consumers.

Genetic engineering and plant breeding are two of the available tools that may be used to enhance crop resistance to stressful conditions. However, these strategies include time-consuming and costly processes, and they are not always positively perceived by the consumer market.

In this context, an alternative option for increasing agricultural productivity and overcoming various environmental stresses includes the deliberate use of microbial biofertilizers. These microbes offer several advantages to other approaches, they are typically non-toxic and are rarely associated with resistance development by the target organism.

Prevalence of different organisms in soil

Soil contains many micro- (viruses, bacteria, algae, fungi, protozoa, and nematodes) and macro- (earthworms, myriapods, and insects) organisms, whose population density varies according to the taxonomic group considered. Among microorganisms, fungi are dominant in soil as their amount is estimated to reach 10^5 – 10^6 cells/g of soil with a biomass of a 100–1500 g/m². On the other hand, the bacterial density approximates 10^8 – 10^9 cells/g of soil, but due to their relatively small size, their total biomass is 2–3 times less than that of fungi (Glick, 2020). The number of microorganisms in soil changes with land management, as well as soil depth. Because of their high tolerance level to disturbance, bacteria and protozoa are prevalent in tilled soil, while fungi and nematodes dominate in untilled soils. According to Torsvik et al. (1990), 1 g of soil contains up to 1.5×10^{10} bacterial cells with ~40,000 different species, of which fewer than 1% are able to grow and develop colonies on artificial media. The availability of organic substances and oxygen decrease through different soil horizons: consequently, the population density of microorganisms decreases with depth in soil. Soil biomass, together with soil biodiversity are the main drivers of ecosystem functions. Thus, greater soil biodiversity is expected to lead to more stable ecosystem functioning. Soil microbial diversity has often been considered a mysterious black box and it has been only with the development of molecular tools, and more recently, -omics techniques that this box has been opened.

Long-term relationship (mutual dependency) between soil microbes and plants

Plants evolved during the Mid-Ordovician period, ~460 to 470 million years ago. Since then, a huge number of diverse microorganisms established interactions with land plants, leading to colonization with different degree of intimacy.

Mycorrhizal fungi are believed to have co-evolved with their host plants since the Early Devonian (~393 to 419 million years ago). At that time, plants were very simple, lacking leaves and roots, being characterized by a rhizoid devoted to nutrient uptake and living in a hostile environment. Interestingly, fossil plants of this type recovered in Scotland have been found to be associated with fungi able to produce arbuscule-like structures like those of the Glomeromycotina. It is reasonable to think that one factor that motivated the development of mycorrhizal symbiosis was the need of both partners to survive in such a hostile environment.

Within bacteria, several taxonomic groups can fix atmospheric nitrogen, and this widespread ability suggests that occurrence of multiple independent regulatory molecular mechanisms evolved through convergent evolution. According to a second hypothesis, Angiosperms belonging to the nitrogen-fixing clade developed a predisposition to nodulate, thus leading to the full establishment of the legume-rhizobia symbiosis (Martin et al., 2017).

Recent data indicate that plants actively recruit their associated microorganisms from the soil, rhizosphere, phyllosphere, anthosphere, spermosphere and carposphere (Gamalero and Glick, 2020). This intricate net of interactions connecting the plant host with its microbiome and all the members of the microbiota to each other is called a “holobiont”. Beneficial microorganisms and plants have interacted and facilitated one another's growth for around 50 million years. While most soil microorganisms and plants can grow and develop on their own, their survival and persistence are greater when they cooperate, especially when facing harsh environmental conditions.

Plant growth-promoting bacteria: Rhizospheric, endophytic, mutualistic symbiotic, phyllospheric

Plants host microorganisms in and around all their tissues. The rhizosphere (the area around the plant roots) is characterized by an intense exudate release by plant roots (mainly composed of organic acids, sugars, amino acids, fatty acids, and vitamins) that attracts a large amount of microbial biodiversity. The phyllosphere (the surface of leaves and stems) is a relatively unfavorable environment for bacteria, being subjected to extremely variable temperature, radiation, and fluctuating water activity. Microorganisms living close to or on the surface of plant tissues are defined as epiphytes, whereas microorganisms able to colonize the internal plant tissues (stems, leaves, roots, flowers, fruits, and seeds) are called endophytes. Symbiotic mutualistic relationships can be established between plants and specific group of bacteria. For example, the symbiosis between various strains of nitrogen fixing rhizobia and about 15,000 different legume species is one of the oldest and most studied. Once an association between the plant and the microbiota is established, the microorganisms may cause beneficial, neutral, or detrimental interactions with the host plant.

Bacterial community structure in the rhizosphere can vary according to the plant species, its phenological stage and health, as well as to environmental and soil parameters. However, the core microbiome, a group of microbial taxa or genes that are shared by all or most local plant species, is generally composed of alpha and beta Proteobacteria followed by Actinobacteria, Firmicutes, Bacteroidetes, Planctomycetes, Verrucomicrobia, and Acidobacteria. Rhizodeposition selects the associated microbiota but in turn this affects the composition of root exudates.

Those bacteria colonizing the phyllosphere are very well adapted to the low nutrient availability and mainly colonize the underside of the leaf on veins, hairs, stomata and glandular trichomes. As for the rhizosphere, there is a core microbiome but composed mainly of alpha and gamma Proteobacteria, followed by Bacteroidetes and Actinobacteria. The physiological group of methylotrophs are quite abundant and typically present on the leaves where they use C1 compounds (i.e., one carbon atom molecules, thus excluding a C—C bond) such as methanol and methylamine as carbon sources. Moreover, lactic acid bacteria dominate the phyllosphere of several plants in the Mediterranean area especially during the summer season (Remus-Emsermann and Schlechter, 2018).

Finally, the endosphere, represented by the internal plant tissues, are typically colonized by non-pathogenic bacterial strains originating mainly from the bulk soil or the rhizosphere and entering through cracks or lateral root branching junctions. This type of horizontal transmission of beneficial bacteria may represent an advantage for the plant that recruits a diverse set of symbionts, thus leading to a prompt response to stressful conditions. Frequently, the penetration into the plant tissues is supported by the release of lytic enzymes degrading the plant cell wall. Once inside the apoplastic space, bacteria replicate reaching densities up to 10^7 – 10^8 colony forming units (cfu) per gram of tissue fresh weight. At the root level, these bacteria can spread to the xylem vessels and then are translocated towards the epigeous portion of the plant. It should also be considered that the possible inheritance of bacterial endophytes is through vertical transmission. If a seed endophyte is a plant beneficial bacterial strain, it is reasonable to suggest that a form of mutualism has been established between the bacterial strains and the plant host (Frank et al., 2017).

The relationship established between the host plant and the members of the bacteriome can be very diverse according to the final effects on the plant growth (neutral, positive, or deleterious) (Fig. 1). Those bacteria involved in positive plant-microbe interactions, leading to beneficial effects on plant development and health are defined as Plant Growth-Promoting Bacteria (PGPB) (Glick, 2020). The mechanisms by which PGPB improve plant growth, health and increase yield are described in the following sections.

Fig. 1 A general overview of plant growth-microbial promoters residing in the phyllosphere, endosphere and rhizosphere. (A) Beneficial interactions that improve plant growth and fitness (i.e., modulation of phytohormones, nutrient uptake improvement, etc.); (B) Biocontrol of pathogens is also carried out by plant growth promoters, and indirectly, improve the plant health; (C) Harmful interaction exerted by pathogens towards the plant; (D) Neutral or commensal microbes interacting with the plant or other microbes.

Fig. 2 Schematic overview of the main mechanisms used by PGPB to promote plant growth. Direct mechanisms are based on plant nutrition improvement through nitrogen fixation, mineral solubilization (mainly phosphate and potassium) and phytohormones synthesis such as auxins, gibberellins and cytokinines. Indirect mechanisms involved production of antibiotics (2,4-diacetylphloroglucinol, pyoluteorin, etc.), lytic enzymes such as chitinases and cellulase, cyanuric acid and induced systemic resistance (ISR). The synthesis of iron chelators (siderophores) and of the enzyme 1-aminocyclopropane-1-carboxylic acid are involved in both direct and indirect mechanisms of plant growth promotion.

Mechanisms

While direct mechanisms carried out by PGPB enhance plant growth in the absence of pathogens (mainly through nutrient uptake and phytohormone concentration modulation), the indirect mechanisms of plant growth promotion consist of biocontrol of deleterious microorganisms (by antibiosis, lytic enzyme release, induced systemic resistance, siderophore and cyanide production) (Fig. 2).

Direct mechanisms

N fixation

The amount of nitrogen gas in the atmosphere is very high (~78%). However, plants are unable to use nitrogen in this form, therefore N₂ needs to be reduced to ammonia before becoming part of macromolecules such as proteins and nucleic acids.

Biological nitrogen fixation (BNF) is mediated by some free living and symbiotic bacteria that can convert atmospheric nitrogen into plant available ammonia through an energy expensive reaction mediated by the enzyme complex nitrogenase. While free-living nitrogen-fixing bacteria include several bacterial species that are associated with plant roots, symbiotic nitrogen fixers include a limited range of rhizobia, each specific to one or a few legume species. Although quantification of the BNF contribution can be problematic, it has been estimated that ~80% of the biologically fixed nitrogen comes from the legume-rhizobia symbiosis. However, under appropriate conditions, the contribution of free-living nitrogen fixers to plant nutrition can be quite significant, reaching 60 kg N ha⁻¹ year⁻¹ (Aasfar et al., 2017).

Nitrogen is one of the macronutrients limiting crop yield. Consequently, agricultural crops are highly dependent on the provision of fixed nitrogen in chemical fertilizers. BNF provides a significant fraction of the available nitrogen to the total plant requirements, therefore decreasing the need for synthetic nitrogen fertilizers during plant growth (Masson-Boivin and Sachs, 2018). Included in the wide range of bacteria that are able to fix nitrogen are several genera of cyanobacteria; the symbiotic genera Rhizobia, Sinorhizobium, Bradyrhizobia, Mesorhizobium and Frankia; rhizospheric and endophytic genera Azospirillum, Azotobacter, Klebsiella, Bacillus and Pseudomonas (Glick, 2020).

Fe sequestration

Despite its great abundance within the earth's crust, in aerobic soils, iron occurs mostly in precipitated forms making the amount of this element available to organisms very small (10^{-7} to 10^{-23} M at pH 3.5 and 8.5, respectively). However, iron is required by both plants and soil microorganisms (10^{-4} to 10^{-9} and 10^{-5} to 10^{-7} M, respectively), leading to an intense competition for this nutrient, especially in the rhizosphere where plant, bacteria, and fungi coexist. Many bacteria respond to iron starvation by synthesizing (i) low-molecular weight iron chelators, called siderophores, with exceptional affinity for ferric iron and (ii) membrane receptors that bind and internalize the ferri-siderophore complex. According to their chemical structure, siderophores are classified into catecholates, hydroxamates, and carboxylates. Although the capability of synthesizing siderophores is widely distributed among bacteria and fungi, mixed ligands produced by fluorescent pseudomonads (i.e., pyoverdines, pseudobactins and pyochelin) are the most studied. Siderophores have a role in improvement of plant nutrition since they supply iron to plants that are able to uptake the bacterial ferri-siderophores complex. Moreover, the increased amount of iron available to plants and beneficial soil microorganisms may lead to the proliferation of beneficial microbes in soils, thus affecting the composition of soil microbiota (Saha et al., 2016).

P and K solubilization

While the amount of phosphorus (P) is typically between 400 and 1200 mg kg⁻¹ of soil the availability of phosphorus in a soluble form (i.e., phosphate ions, H₂PO₄⁻ and HPO₄⁻²) is very small at ~1 mg kg⁻¹ or less. Since P is one of the macronutrients that can limit plant growth it is usually introduced into agricultural soils as a chemical fertilizer. However, only 10–25% of this added phosphate is generally used by plants since it forms metal cation complexes that precipitate in soils. In this context, phosphate solubilizing bacteria (PSB) including species of Pseudomonas, Agrobacterium, Bacillus, Azotobacter, Burkholderia, Enterobacter, Erwinia, Kushneria, Paenibacillus, Ralstonia, Rhizobium, Rhodococcus, Bradyrhizobium, Sinomonas, and Thiobacillus (Alori et al., 2017) able to solubilize inorganic phosphates through the synthesis of organic acids that release soluble phosphate, or able to solubilize organic phosphates by synthesizing enzymes that break down these compounds may be useful (Alori et al., 2017).

After N and P, potassium (K) is one of the main essential macronutrients for plant growth. Since the amount of potassium in a soluble form in soils is usually very low, plants can show potassium deficiency symptoms such as poorly developed roots, leaf chlorosis localized on the margin of the dorsal side, reduced plant biomass and yield. Solubilization of potassium rock by PSB occurs through the release of organic acids lowering of the pH. Strains belonging to the species Acidithiobacillus ferrooxidans, Paenibacillus spp., Bacillus mucilaginosus, Bacillus edaphicus, and Bacillus circulans showed this interesting ability which, together with other plant beneficial traits, can lead to a reduction of the use of chemical fertilizers in agricultural soil management (Etesami et al., 2017).

IAA production

Among the auxins, indole-3-acetic acid (IAA) is the most common and the most studied. As often happens for hormones, different amounts of auxins show different impacts on plant growth. For plants, the main consequences related to auxin are the modulation between cell division and extension, differentiation of plant cells and tissues, seed and tuber germination, increases in the rate of xylem and root development, increases in the emergence of lateral and adventitious roots, mediation of responses to light and gravity, florescence, and fructification of plants. IAA also affects photosynthesis, pigment formation, biosynthesis of various metabolites, and resistance to stressful conditions.

The effect of auxin in planta on root elongation is dose dependent. Moreover, the effective concentration of auxin in planta depends on the plant species and on the sensitivity of the target tissue. Bacterial auxin levels below an optimal amount may have little to no effect on plant development, while levels above this concentration of hormone can inhibit growth.

The ability to synthesize IAA is a common trait in many soil bacteria, both PGPB and pathogens, belonging to a wide range of different taxonomic groups. There are seven known metabolic pathways leading to IAA biosynthesis in bacteria, with five of them based on tryptophan as a precursor (Duca et al., 2014). Tryptophan synthesis is energy requiring for bacterial cells. Consequently, its concentration inside the cell is small, and the bacterial cells need to find a balance between the use of this amino acid for protein synthesis and the production of IAA. To obtain large amounts of IAA, bacterial cells use the tryptophan exuded by the plant root systems. IAA of bacterial origin supplements the endogenous plant IAA pool potentially leading to different and opposite

consequences (stimulation or suppression) for plant growth and root morphogenesis. One of the most relevant consequences of bacterial IAA synthesis is an increase in lateral and adventitious roots, leading to improved nutrient uptake and, in turn, to the enhancement of root exudation which attracts microorganisms that colonize the roots. Therefore, IAA, together with a plethora of other molecules released by plants, is involved in the build-up of the plant microbiota (Keswani et al., 2020).

Gibberellin synthesis

Gibberellins are phytohormones produced by higher plants, fungi, and bacteria, with a chemical structure based on diterpenoid acids consisting of an isoprene residue. Affecting both cell division and elongation, gibberellins play an important role in several stages of plant development such as seed germination, stem elongation, flowering, fruit setting, and delay of senescence in many organs. Moreover, they regulate root hair abundance thus positively impacting nutrient uptake efficiency. The ability to synthesize gibberellin is quite common in both Gram positive and negative bacterial strains belonging to the genera *Azospirillum*, *Azotobacter*, *Arthrobacter*, *Azospirillum*, *Pseudomonas*, *Bacillus*, *Acinetobacter*, *Flavobacterium*, *Micrococcus*, *Agrobacterium*, *Clostridium*, *Rhizobium*, *Burkholderia*, and *Xanthomonas*. Plant growth stimulation by PGPB able to produce gibberellins has been widely demonstrated and is often associated with other plant beneficial physiologic traits as well as the interplay with other hormones and the modulation of the overall hormonal balance in plants (Salazar-Cerezo et al., 2018).

Cytokinin synthesis

The chemical structure of cytokinins is based on N6-substituted aminopurine. These molecules are involved in diverse plant physiological processes, such as cell division, interruption of the quiescence of dormant buds, activation of seed germination, promotion of branching, root growth, accumulation of chlorophyll, leaf expansion, and delay of senescence. One plant response to cytokinins is the modification of cell size and shape due to regulation of the expression of protein expansion, which determines the loosening of plant cell walls and the subsequent facilitation of plant cell expansion.

Although several PGPB strains including *Azotobacter*, *Azospirillum*, *Rhizobium*, *Bacillus*, and *Pseudomonas* spp., can synthesize this hormone, cytokinins synthesized by bacteria have received much less attention than the bacterial synthesis of IAA. In fact, the synthetic pathway of bacterially encoded cytokinins and their effect on plant development are not yet completely understood. Finally, because of loosening plant cell walls, bacterial cytokinins can increase the release of root exudates that function as attractants for many bacteria, including plant beneficial ones therefore increasing the possibility of being efficiently colonized by PGPB.

ACC deaminase

The enzyme ACC deaminase can degrade the ethylene precursor, ACC, to ammonia and alpha-ketobutyrate and is widespread in soil bacteria and some soil fungi. By breaking down some of the ACC in plants, this enzyme can significantly lower plant ethylene levels and thus decrease the extent of ethylene inhibition of plant growth, especially following various biotic and abiotic stresses.

The gaseous phytohormone ethylene, produced in all higher plants, mediates a wide range of plant responses and developmental steps. It is involved in seed germination, tissue differentiation, formation of root and shoot primordia, root branching and elongation, lateral bud development, flowering initiation, anthocyanin synthesis, flower opening and senescence, fruit ripening and degreening, production of volatile organic compounds responsible for aroma formation in fruits, leaf senescence, leaf and fruit abscission, Rhizobial stimulation of nodule formation, mycorrhizal fungi-plant interaction, and the response of plants to a wide range of biotic and abiotic stresses. In some cases, ethylene is stimulatory while in others it is inhibitory, depending upon the amount of ethylene that is produced.

Exposure of plants to stressful conditions (either biotic or abiotic) results in the overproduction of plant ethylene levels. High ethylene levels can cause a plant to incur increased damage as a result. For example, when plants are infected by phytopathogens, a large fraction of the damage to the plant is due to high ethylene levels. According to the model proposed by Glick et al. (2007), following the onset of an environmental stress the plant produces a small amount of ethylene leading to the transcription of defensive genes. Subsequently, if the stress becomes more intense or persists over time, the ethylene level in the plant increases and induces the initiation of processes inhibitory to plant growth and survival such as senescence, chlorosis, and abscission. Bacteria able to synthesize ACC deaminase, cleave the immediate ethylene precursor, ACC, into ammonia and -alpha-ketobutyrate, lowering the second ethylene peak, thus improving plant tolerance to a wide range of stresses including stress caused by pathogen infection of plants.

Indirect mechanisms

Antibiotics

The rhizosphere is a hot spot where the members of the microbiota are constantly competing for nutrients. Therefore, the synthesis and release of antibiotic molecules is a survival strategy for some rhizosphere microorganisms to help them to successfully colonize this ecological niche. As observed during take-all decline, wheat plants infested with the phytopathogenic fungus *Gaeumannomyces graminis* var. *tritici* (Ggt) through the exudates released by necrotized roots, recruit fluorescent *Pseudomonas* able to produce the antibiotic 2,4 diacetylphloroglucinol which inhibits the growth of the phytopathogenic fungus. Fluorescent *Pseudomonas*, releasing 2,4 diacetylphloroglucinol, phenazine-1-carboxylic acid, phenazine-1-carboxamide, pyoluteorin, pyrrolnitrin, oomycinA, and pyocyanin and the *Bacillus* group, synthesizing surfactin, iturins, fengycins, kanosamine and zwittermycin A are two of the main producers of antibiotics in the rhizosphere. All these molecules have been tested both in *in vitro* and *in vivo* conditions and showed their ability to suppress diseases induced by fungal pathogens (Santoyo et al., 2021a, 2021b, 2021c).

HCN

According to the temperature, the oxygen availability and the bacterial strain involved, several bacterial species, mainly fluorescent pseudomonads, Burkholderia and Chromobacterium, can synthesize different amount of cyanide in the rhizosphere. The chemical reaction is based on glycine decarboxylation, involving the enzyme cyanuric acid synthase releasing CO₂ and HCN, the latter being toxic to phytopathogens through respiration inhibition at the cytochrome *c* oxidase level.

Bacteria able to carry out this reaction are usually resistant to cyanide. For pseudomonads, a **thiosulfate: cyanide sulfurtransferase** (rhodanese) converts cyanide to **thiocyanate** reducing the toxicity for these cells. In addition to its use for biocontrol of phytopathogens, HCN is involved in metal chelation, thereby increasing the amount of phosphate available for plant growth (Anand et al., 2020).

Cell wall degrading enzymes

Lytic enzymes released by PGPB such as β -1,3-glucanases, lipases, cellulases, and chitinases are involved in endosphere colonization as well as in nutrient cycling in soil but, due to the cell wall composition of these PGPB, they are among the main actors of antagonism towards fungal pathogens. Moreover, lytic enzymes produced by PGPB can damage both egg shells and cuticles of plant parasitic nematodes which are composed of a protein matrix and a chitin and a proteinaceous membrane, respectively. These two structures are the target of chitinases, proteases, peptidyl-peptide hydrolases, and gelatinolytic proteins (Gamalero and Glick, 2020).

Siderophores

In addition to being involved in plant growth promotion, siderophores can inhibit soil-borne diseases. Bacteria able to synthesize these chelating molecules can outcompete pathogenic microorganisms that are unable to synthesize iron chelators, or produce only a low level of siderophores, or release siderophores with a low affinity for ferric iron. Moreover, bacterial siderophores can sometimes induce systemic resistance in plants infected by pathogens. Due to their ability to bind a wide array of toxic metals, such as Cr³⁺, Al³⁺, Cu²⁺, Eu³⁺, and Pb²⁺, siderophores are often involved in detoxification of heavy-metal-contaminated substrates, becoming an effective and eco-friendly tool for heavy metal remediation (Swapan et al., 2020).

Induced systemic resistance

Plant beneficial bacteria can also boost intrinsic plant defenses against pathogens through induced systemic resistance (ISR) which also affects the non-colonized parts of the plant. This allows the plant to become less susceptible to further infections by a wide variety of pathogens including microbes, nematodes, and insects. The mechanism is based on microbial specific elicitors called microbe-associated molecular patterns (MAMPs), such as bacterial flagella, siderophores, antibiotics, biosurfactants and volatile organic compounds, which are detected by immunosensors located on the extracellular side of the plant cell plasma membrane known as pattern recognition receptors (PRRs). When signal perception occurs, the response of the plant is quite rapid, and typically within a few minutes the plant produces reactive oxygen species, phytoalexins, antimicrobial enzymes, phenolic compounds, or pathogenesis-related proteins, together with cell wall morphology changes. Although the triggering of ISR is strain and plant species dependent, this bacterial ability represents an innovative alternative to chemical control of plant diseases as well as biotic stresses (Meena et al., 2020).

Plant growth-promoting fungi

Mycorrhizal fungi

Soil-dwelling mycorrhizal fungi form a complex symbiosis with plant roots, forming a mycorrhiza. As this relationship may be up to 450 million years old, the communication between the two organisms is very intimate (Strullu-Derrien et al., 2018). The first studies of this symbiosis carried out by Frank (1885) distinguished two types of mycorrhizal fungi-plant interactions, those that could penetrate the cell wall (endomycorrhizae) and those that merely surrounded the roots (ectomycorrhizae). Later studies were able to determine that ectomycorrhizal fungi (ECM) mainly formed associations with trees and shrubs, whereas endomycorrhizae or arbuscular mycorrhizae (AM) are formed through a much wider range of associations with plants that are not only part of natural ecosystems, but also with crops of agronomic interest. The main contributions of arbuscular mycorrhizal fungi (AMF) to plants are direct by improving their nutrition (mainly P and poorly mobile micronutrients) as well as to increase their natural defenses against pathogens and herbivory, and indirect by enhancing soil structure and thereby improving water retention. Moreover, mycorrhizal fungi can form complex and abundant interactions with the roots of the plant, extending their area by a large percentage to obtain nutrients and water from the soil.

Trichoderma

Fungi belonging to the genus *Trichoderma* (teleomorph *Hypocrea*), which includes about 100 species, occur in all climatic zones, both in soil and the rhizosphere, and are usually classified as opportunistic, avirulent plant symbionts, and mycoparasites of plant pathogenic fungi. Thus, *Trichoderma* spp. are considered as promising fungal biocontrol agents. Plant inoculation with *Trichoderma* can provide several advantages, such as the suppression of soil borne disease carried out by phytopathogenic fungi, and the consequent improvement of plant health and growth. The main mechanisms used by *Trichoderma* spp. are based on efficient root colonization leading to niche exclusion against other possible deleterious root colonizers, antibiotic molecules production, increased resistance of plants through induced localized acquired resistance (LAR) and induced systemic resistance (ISR) and,

typically, on the synthesis of constitutively expressed fungal cell wall lytic enzymes. Several lytic enzymes (cellulase, chitinase, β -1,3 glucanases and proteases) synthesized by *Trichoderma* strains have been isolated, and their activity has been ascertained against both fungal pathogens and fungus-like organisms whose cell walls lack chitin e.g., *Pythium* and *Phytophthora*. The microparasitic action of *Trichoderma* begins with host recognition, through sensing oligochitin that are components of the pathogen cell wall. Subsequently, *Trichoderma* grows chemotropically in a targeted manner and its hyphae contact the pathogen mycelium. Then, the hyphae of *Trichoderma* synthesize lytic enzymes which induces the formation of pores leading to hyphae collapse and to the release of cellular contents that become nutrients for the biocontrol agent. Besides parasitizing fungi and oomycetes, several *Trichoderma* species can behave as parasites against eggs and larvae of nematodes and insects. Finally, many strains of *Trichoderma harzianum* and *T. atroviride* are efficient plant growth promoters, significantly increasing crop productivity (Sood et al., 2020).

Microbial consortia

Plants during their development and growth can be stimulated by associated microbiota. The microbiomes associated with plants can interact with each other and have consequences for their hosts. Some interactions that occur between the microbiomes are commensal, amensal, neutral, competition or predation, and cooperation. The interactions that are important for plant growth promotion are those where two or more organisms cooperate with each other to exhibit additive or synergistic actions. Additive interactions add up to twice the activity, while synergistic interactions can have actions that are more than twice the individual activities. Thus, a microbial consortium can be defined as a mixture of two or more microorganisms that work additively or synergistically to promote plant growth (Santoyo et al., 2021a, 2021b, 2021c).

In the literature, different mixtures of microorganisms have been reported that can function as consortia that benefit the growth of different plant crops under different growing conditions, whether in laboratory, greenhouse, or open field studies. Three types of consortia are described below that involve the joint application of bacteria-bacteria, bacteria-mycorrhizal fungi, and bacteria-*Trichoderma*.

Bacteria-bacteria

One of the widely studied consortia includes those where two or more bacterial groups participate in promoting plant growth. As mentioned above, PGPB exhibit different mechanisms of action, including nitrogen fixation, production of iron chelating compounds (siderophores), production of phytohormones, among others. Sometimes a bacterium can be very efficient in only one of these mechanisms. For example, rhizobia are excellent nitrogen fixers in legume plants, such as beans or alfalfa, but their antifungal or antibacterial activities are generally not very efficient. However, this deficiency can be supplied by another bacterial genus, such as *Pseudomonas* or *Bacillus*, bacterial genera with strong antagonistic activities towards plant pathogens, in addition to having ISR activities. Such activities are due to a diverse production of antimicrobial compounds such as antibiotics and lytic enzymes. On the other hand, these non-rhizobial bacterial groups are incapable of forming nodules on the roots of legumes. In this example, each bacterial group contains different mechanisms for promoting plant growth and their activities are complementary.

Bacteria-mycorrhizal fungi

Another example of microbial consortia where there is a complementarity of activities is between bacteria and mycorrhizal fungi. Bacteria have excellent activities to promote plant growth directly and indirectly, while mycorrhizal fungi are characterized by their effective improvement of plant nutrition. AMF are also widely known for improving the physical properties of the soil, since they form aggregates that allow them to retain more water, avoiding water stress in plants. The glomalins produced by AMF may be relevant for this function, which is unknown in bacteria. AMF can also function as soil bioremediators, thus improving soil health. Therefore, consortia composed of mixtures of bacteria and mycorrhizal fungi, can have beneficial effects on plants that are subjected to abiotic or biotic stress. For example, a consortium including the PGPB *Variovorax paradoxus* strain 5C-2, plus a nodule-forming and nitrogen-fixing strain, *Rhizobium leguminosarum* RCAM1066, and an arbuscular mycorrhizal fungus of the genus *Glomus* were able to confer resistance and improve the growth of pea plants (*Pisum sativum* L.) in soils contaminated with cadmium (Belimov et al., 2020).

Bacteria-Trichoderma

There is considerable evidence of the role played by microbial consortia composed of PGPB and different species of *Trichoderma*. Some of the synergistic functions that have been proposed include: stimulation of plant growth under normal and stress conditions, increase in plant nutrition, improvement of the root system, induction of ISR, and biocontrol of potential phytopathogens. Both groups of organisms contain species that, in addition to exhibiting the aforementioned beneficial mechanisms, are also excellent competitors in environments, such as the rhizosphere. The capabilities of this type of consortium have been proven not only in laboratory experiments, also in the field. Such is the case of the co-inoculation of *Brevibacterium halotolerans* and *Trichoderma harzianum* that synergistically enhanced the growth and oil yield in *Mentha arvensis* under both greenhouse and field conditions (Singh et al., 2019). There is evidence that PGPB and *Trichoderma* consortia carry out additive and synergistic interactions that boost the growth and health of crop plants (Kong et al., 2018; Santoyo et al., 2021a, 2021b, 2021c).

Commercialization of plant growth-promoting soil microorganisms

Bacteria

The selection of new PGPB as biofertilizers or biocontrol agents is based on a complex procedure consisting of: (i) isolation of microorganisms from soil, or different plant compartments, (ii) characterization of the bacterial physiological and metabolic activities involved in plant growth promotion, (iii) assessment of the effect of the PGPB on the growth of plants cultivated both under controlled and greenhouse conditions, and under both optimal and stressed environmental conditions, (iv) determination of the ecological safety of the PGPB, (v) inoculum formulation to satisfy the farmer's needs, and ensuring bacterial survival and viability on storage and shipping, and (vi) marketing and registration of the bacterial strain(s). However, it is rare to find a precise match between the traits determined *in vitro* and the behavior observed on plant growth in the field. Moreover, the use of microorganisms in agriculture is regulated in different countries by measures that ensure the efficacy of the microbiological product, as well as the quality control check and the protection of the intellectual property (for a recent review on regulatory policies for microorganism use, see Sundh et al., 2021).

The global biofertilizer market is expected to reach \$3.5 billion US by 2025 with free living and symbiont nitrogen fixing bacteria as the main commercial products (80%) (Basu et al., 2021). Recently, several manufacturers have begun to commercialize consortia based on a mixtures of rhizobia strains and rhizospheric or endophytic PGPB, bacteria and AMF, bacteria and plant growth-promoting fungi. Given that plant microbiomes contain hundreds to thousands of different microbes, complex natural consortia are beyond the ability of our current technology. On the other hand, it is also true that thanks to the recent development of -omics techniques, within the next 10–15 years, researchers will be able to formulate stable and efficacious complex microbial consortia based on a limited number of key microbial species.

Fungi

The method generally used to produce AMF inocula on a large-scale is based on systems of trap plant cultivation on substrate or in aeroponic boxes, as well as under *in vitro* conditions. Overall, the procedure is labor-intensive, and the costs related to the maintenance and reproduction of single AMF isolates, the formulation of the carrier and the management of the optimal conditions for the establishment of the mycorrhizal symbiosis are quite substantial. However, the benefits from mycorrhizal inocula are remarkable and can be categorized as both marketable (so that they can be evaluated as economic gain) and non-marketable. The first group includes improvement of mineral nutrition, productivity enhancement, reduction of watering and pesticide cost, and facilitation of seedling establishment. On the other hand, the improvement of food nutritional value, reduction of soil erosion and nutrient leaching, soil phytoremediation of organic and inorganic pollutants as well as the social benefits of education are all included in the second category (Gupta and Abbott, 2021). Similar to bacterial inoculants, a great increase in the number of companies working on mycorrhizal fungal technologies and associated products and services occurred in the past few decades. In 2019, the AMF-based biofertilizer market was evaluated to be close to \$268.8 million US, and is expected to reach \$621.6 million US by 2025. However, the increase of the AMF inocula market is accompanied by inconsistent performance under field conditions.

A thorough knowledge of the factors that affect mycorrhizal inocula efficacy in agroecosystems including climate conditions, plant host species, season, geographic location, soil characteristics, or even the good quality in the preparation of the inoculum should allow the achievement of the expectations from AM symbiosis.

Future prospects

The way to facilitate plant growth and feed the growing world population by judiciously employing the use of plant growth promoting microorganisms is challenging but promising. Crop plants typically recruit beneficial microorganisms from the soil and (as best as they can) exclude phytopathogens. These beneficial microorganisms (mostly bacteria and fungi), using a wide range of mechanisms, facilitate plant growth. Beneficial microorganisms may act individually or in concert with one another. As our knowledge of the fundamental mechanisms employed by these microorganisms continues to increase so does our ability to utilize these microorganisms in sustainable agricultural practice. In the future, it is hoped that we will eventually be able to limit or replace the bulk of the potentially deleterious chemicals that are using in agriculture and replace them with well-characterized and well-understood soil microorganisms.

Abstract

Soil microbial inoculants are microorganisms that are used as sustainable alternatives to conventional inorganic fertilizers (biofertilizers), carry out specific functions including biocontrol of pests and diseases (biopesticides), or are used for bioremediation and enhancement of soil characteristics. Some soil inoculants such as nitrogen-fixing rhizobia have a long and successful history of use, but many new products perform inconsistently in the field. Better understanding of how soil inoculants interact with plants and the soil environment is helping to improve their effectiveness, as is the development of improved formulations and delivery systems.

Key points

- Significant gains in crop productivity have been achieved in part through increased use of agrichemicals including synthetic fertilizers and pesticides.
- Over-use of synthetic fertilizers is linked to deterioration of water quality and there is growing concern over pesticide residues accumulating in food chains and causing population decline in beneficial species such as pollinators
- Beneficial soil microorganisms capable of improving the supply of nutrients in soil or reducing the impact of soil pests and diseases can be used to inoculate soil.
- Microorganisms applied to soil face many challenges to become established in soil so they must be formulated and applied carefully.
- Selection of multi-functional microbial consortia is a promising approach to development of future inoculant products.
- Soil microbial inoculation provides a sustainable approach toward reduction of some synthetic agricultural inputs.

Introduction

Demand for food to support the rapidly increasing global population has driven widespread and ongoing intensification of agricultural production with greater crop productivity achieved largely through improved plant varieties and heavy use of agrichemicals. The environmental impacts from over-use of agricultural inputs such as fertilizers and pesticides are increasingly evident, for example nitrogen and phosphorus from agricultural fertilizers has led to significant deterioration of water quality across the globe. Detection of pesticide residues in food chains and within previously pristine environments is raising concern and has led

to the de-registration of many effective but environmentally persistent and highly toxic synthetic pesticides, leaving growers with reduced options for management of crop pests and diseases. At the same time, intensification of agriculture has led to significant global soil loss and degradation. Given the importance of soil in sustaining the world's human population, there is a clear need for more sustainable approaches that maintain agricultural production while better protecting the environment.

Decades of (predominantly laboratory) research on a wide range of soil and plant-associated microorganisms has demonstrated their potential benefits, and current pressure to develop more sustainable agriculture has led to a resurgence in research interest and a growing global industry around the use of microbial inoculants in agriculture. Soil microbial inoculants are defined as bacteria, fungi (and more rarely other microorganisms) that are introduced into soil to perform a specific function such as biocontrol or plant growth promotion (O'Callaghan et al., 2022).

Many soil and plant-associated microorganisms have beneficial properties that can be utilized to provide much needed solutions for agriculture (Fig. 1). For example, some strains can act as biopesticides or biocontrol agents to protect emerging seedlings from soil-borne pests and diseases, providing an alternative to synthetic pesticides. Others have the capacity to enhance plant uptake of soil nutrients and are referred to as biofertilizers and are a viable option as alternatives to conventional inorganic fertilizers. The mechanisms that underpin the beneficial impacts of microbial inoculants are varied and complex, so successful use of inoculants depends heavily on a sound understanding of the ecology of the microorganisms and their interactions with the soil environment.

Functions of soil microbial inoculants

Biofertilizers

As nitrogen (N) is the essential plant nutrient needed in the greatest amount, it is not surprising that nitrogen-fixing microorganisms are the most widely used soil microbial inoculants. Plant-associated symbiotic rhizobia have been used extensively in leguminous crops where their ability to meet plant N requirements has been shown to significantly reduce, and sometimes, eliminate the need for synthetic N fertilizers. For many legume varieties, inoculation with the correct rhizobial partner is essential for crop establishment where the required strain is not already present in soil and legume inoculation has been standard agricultural practice since the middle of the last century. In Brazil, inoculation of soybean with N-fixing *Bradyrhizobium* spp. can meet the N demand of the crop, eliminating the need for N fertilizers (a significant cost saving for farmers) with concomitant reductions in greenhouse gas emissions associated with fertilizer use (Zilli et al., 2021).

In addition to many plant-associated rhizobial inoculants, free-living N-fixing microorganisms such as *Azospirillum* and *Azotobacter* spp. are frequently used as soil inoculants. *Azospirillum* is one of the most studied genera of plant growth-promoting bacteria (PGPB) in the world and there are currently over 100 products based on this genus in South America alone (Cassan et al., 2020). Although some strains of *Azospirillum* have an affinity for certain crops, the major advantage of this genus is that useful strains are not always as plant specific as many rhizobia inoculants and can enhance the growth of numerous plant species. While *Azospirillum* is usually unable to supply all the required N for cereal and maize crops, reductions in fertilizer inputs of 25–50% have been reported. Beneficial effects of inoculation with *Azospirillum* result from multiple mechanisms including phytohormone production and stimulation of root growth, as well as N fixation (Cassan et al., 2020). Co-inoculation of soil with both symbiotic rhizobia and *Azospirillum* is also being used to boost crop production, as are other microbial consortia (see below).

With issues around security of supply, the ethics and cost of extraction, and the environmental impacts of non-renewable phosphorus (P) fertilizers on water quality, there is increasing interest in better management of the pool of P existing in soil using P-solubilizing microorganisms. Arbuscular mycorrhizal fungi (AMF) are widely used as soil inoculants, particularly for inoculation of trees and horticultural crops or for use in degraded or disturbed soils to assist plant colonization. AMF increase plant P uptake by physically extending the root systems through extension of the hyphae through soil and through their ability to acquire orthophosphate from soil solution at lower concentrations than roots. Mycorrhizal products have been shown to aid plant survival under stressful conditions, but scientific opinion is divided as to whether AMF inoculants deliver consistent benefits in cropping situations (Ryan and Graham, 2018; Zhang et al., 2019).

A wide range of P-solubilizing bacteria (PSB) have been identified from soil based on their capacity to solubilize sparingly soluble phosphate compounds in artificial media through secretion of low molecular weight organic ions, which acidify the medium. PSB (commonly *Pseudomonas*, *Bacillus*, and *Burkholderia* spp.) are reported to aid in de-sorption of inorganic P and complex organic P compounds from clay particles in soil by acidifying the rhizosphere, thereby increasing the solubility of precipitated inorganic P salts. Some soil microorganisms also produce various enzymes including phytases that enable microbes to access soil P but the relative contribution of microbial enzymes, in comparison with plant-derived soil enzymes remains unknown. While numerous strains have been shown to solubilize P in laboratory assays, it has not been possible to consistently demonstrate a clear link between improved soil P availability by PSB and crop productivity and it is possible that P-solubilizing microbes (PSM) are solubilizing soil P to meet their own requirements, rather than those of the plant (Raymond et al., 2021).

Better results in the field have been achieved with free-living P-solubilizing fungi. For example, Canadian growers reported that inoculation of wheat and canola with *Penicillium bilaii* resulted in average wheat and canola yield benefits of ~6%, but up to 66% (Harvey et al., 2009). While reported yield benefits vary, products based on *P. bilaii* are currently being marketed successfully, for example JumpStart® (Bayer Crop Science, 2022).

Fig. 1 Current and potential uses of soil microbial inoculants: Increased plant nutrient availability through activity of symbiotic and free-living nitrogen-fixing bacteria and solubilization of soil P by bacteria and fungi; enhanced plant tolerance to environmental extremes including induction of stress response pathways in plants; plant growth promotion via many mechanisms, e.g., production of phytohormones; bioremediation by microbial degradation of contaminants and co-inoculation to aid phytoremediation; reduced greenhouse gas (GHG) emissions through microbial activities; protection against soil-borne insect pests and plant pathogens; improved soil structure and water retention. Modified from: O'Callaghan, M., Ballard, R., Wright D. (2022). Soil microbial inoculants for sustainable agriculture: Limitations and opportunities. *Soil Use and Management* doi: 10.1111/sum.12811.

General plant growth promotion and protection against soil-borne pests and diseases

A wide range of plant-growth promoting bacteria and fungi are used as soil inoculants for many agriculturally significant plant species, including legumes, cereals, and vegetable crops. Many studies have reported that application of plant growth-promoting bacteria (PGPB) resulted in significant increases in root and shoot mass and reproductive yields and effects were even greater for above ground traits under drought conditions.

Beneficial microorganisms utilize many different mechanisms to enhance plant growth, including production of phytohormones, siderophores, antibiotics and other secondary metabolites (Lopes et al., 2021). Some also have capacity to protect plants from soil-borne diseases and pests and it is difficult to separate the mechanisms underpinning improved plant growth as in some cases inoculants are likely to be providing multiple benefits to the plant. For example, fungal inoculant products based on *Trichoderma* spp. enhance plant growth by multiple mechanisms including biocontrol of soil-borne pathogens, enhancing plant systemic resistance to pathogens and insects, and increased root proliferation (Schuster and Schmoll, 2010). Because of their multiple modes of action, *Trichoderma* strains are the active ingredient in hundreds of agricultural products commercialized worldwide.

Plant growth-promoting microorganisms (PGPM) used as soil inoculants are most often applied at time of sowing, when they provide protection of seeds and emerging seedlings against soil-borne pests and seed or root rot pathogens. While most often applied early in plant growth, their benefits can sometimes extend well beyond plant establishment, for example treatment of maize seed with two microbial biocontrol agents reduced populations of the pathogen *Fusarium verticillioides* and its associated mammalian-active mycotoxins in harvested grain (Pereira et al., 2011).

Soil inoculants are a good plant protection option when no chemical treatments are available, which is often the case for soil-borne plant pathogens and pests which are notoriously difficult to control. Many soil dwelling pests and pathogens are attracted toward germinating seeds and young roots, resulting in rapid destruction of newly planted crops. Introduction of an effective biocontrol agent directly into the root zone is therefore a useful strategy. This approach also has potential for management of soil dwelling insect pests, which in the past have been managed through application of persistent agrichemicals. Proof-of-concept of soil microbial inoculants for insect pest control has been achieved in the field through application of a soil bacterium (*Serratia entomophila*) for management of a scarab beetle larvae attacking pasture and cereal crops (O'Callaghan, 2016).

Enhanced plant stress tolerance

Abiotic stresses harm plant growth and physiology and reduce yield by obstructing cell metabolism or gene regulation within the cells. Abiotic stresses at play in soils include extreme temperatures (both high and low), moisture stress (drought or floods, rewetting cycles), pH, salinity and presence of heavy metals and other contaminants. Most crop plants don't possess advanced morphological or physiological adaptations necessary to withstand drought or high salinity situations. However, inoculation with selected soil and plant-associated microorganisms can increase plant tolerance to abiotic stress (Goswami and Deka, 2020). As discussed above, plant-growth-promoting bacteria can produce various plant growth regulators and hormones that improve the plant's antioxidant potential and accumulation of osmolytes. For example, a novel root-colonizing salt tolerant strain of *Bacillus* sp. was selected and tested for its capacity to maintain growth of wheat in a gradient of soil salinity (Ansari et al., 2019). Large salt concentrations adversely affected wheat growth and biochemical parameters relevant to photosynthesis, transpiration, and stress response in uninoculated plants, whereas seed yield and protein content of grain was maintained in inoculated plants. Another well-known inoculant, *Azospirillum brasilense*, has been shown to alleviate drought stress by multiple mechanisms including induction of systemic resistance, restricting Na⁺ absorption and increasing K⁺ and Ca⁺⁺ uptake by plants, and induction of root branching and density of root hairs (Fukami et al., 2018).

Efforts have been made to select for inoculants that are themselves tolerant to target abiotic stress. Drought tolerant bacteria produce exopolysaccharides (EPS) on their surfaces which improve water retention in the rhizosphere, protecting the root surface from mechanical damage. Microorganisms that have already evolved tolerance to soil abiotic stresses can also be selected directly from the environments where they are needed as soil inoculants. Acidic soils comprise more than 30% of the global land area and are characterized by a pH value lesser than 5.5 throughout the year. Acidic soils are typically deficient in available beneficial elements including P, molybdenum and magnesium and can contain inhibitory levels of aluminum and iron. Microorganisms survive within acidic soils by maintaining the intracellular levels of elements at near neutral levels or by dispensing with peripheral cellular structures that are in direct contact with the soil acidity. However, microbial inoculants suited to acidic soil conditions are rare, and greatly needed to support plant growth under these conditions.

Bioremediation

Anthropogenic activities, such as mining, intensive agriculture, e-wastes, and use of fossil fuels, can result in soil contaminants reaching hazardous levels. Increasing loss of soil functionality due to contamination by heavy metals, excessive trace element loadings and organic pollutants is a global environmental issue that poses significant risks to human health and both productive and natural ecosystems. Use of soil inoculants for bioremediation of contaminated soils is not new but interest in utilizing microorganisms to effect in situ remediation of contaminated soils has intensified due to the expense of conventional remediation. In particular, the combined use of carefully selected inoculants with site-tailored cropping systems (phytomanagement) is proving a useful tool to help plants cope with soil contamination. Inoculation with plant growth-promoting bacteria and AMF have been

most used, but responses can vary according to specific combinations and with different plant species. For example, some strains of *Burkholderia* sp. have been shown to reduce cadmium accumulation in plants while other research has reported increased mobilization and increased plant accumulation (Guo et al., 2020).

Much better understanding of the efficiency and the mechanisms by which soil inoculants function in complex contaminated soil environments is needed. Recent work showed that a bacterial inoculant *Comamonas testosteroni*, capable of degrading polycyclic aromatic hydrocarbons (PAHs), also increased synergistic effort to degrade PAHs among indigenous soil bacteria (Lu et al., 2022).

Many microorganisms with capacity to degrade various widely used pesticides have been identified but recent research has begun to focus on the use of microbial consortia rather than single strains. Microbial consortia are discussed further below, but in the bioremediation context, it is thought that consortia may be able to degrade pesticides more quickly and efficiently by sharing the metabolic labor to attack and breakdown the molecular structure.

Climate change mitigation

Microbial inoculants potentially offer sustainable solutions to climate change indirectly through their influence on plant growth and delivery of various agroecosystem functions and services, allowing reductions in traditional agrichemicals. Examples of direct mitigation are scarce to date but it is an area of increasing research interest. Reduction of methane emissions from agriculture is a key goal of greenhouse gas mitigation strategies and recent work has demonstrated that co-inoculation of efficient methane-utilizing bacterium *Methylobacterium oryzae* and plant growth-promoting bacterium *Paenibacillus polymyxa* reduced cumulative methane emissions in rice paddy fields (Rani et al., 2021). N₂O-reducing bacteria have also been reported to decrease soil N₂O emissions in soil microcosms and genetically engineered CO₂-fixing microorganisms reduced soil emission of CO₂ by promoting carbon sequestration (in culture only) (Liu et al., 2022).

Enhancing soil characteristics

Soil bioengineering—using microbial inoculants to modify soil chemistry and structure—is a novel approach that has not yet been widely explored. Microorganisms play a critical role in soil formation and soil aggregate stabilization and some EPS-producing bacteria can improve soil aggregation and adherence of soil to plant roots, demonstrating their potential as inoculants. For example, a strain of *Pseudomonas putida* (selected for its ability to survive at low soil moisture potential) colonized the soil adhering to sunflower roots and increased the development of stable soil aggregates. Increased plant biomass and stress tolerance was attributed to plant growth-promoting compounds produced by the bacteria within the biofilm produced on the roots of the seedlings, and through production of EPS which increased soil aggregation, thereby maintaining higher water potential around the roots (Sandhya et al., 2009). Improvements in the macroporosity of soil have been reported with a range of other plant-growth promoting bacteria, suggesting that EPS-producing bacteria could be used as inoculants to regulate water stress (Gouzou et al., 1993). Restoration of soil quality and function is a key goal of rehabilitation at mine sites and the use of microbial inoculants to improve soil aggregation in the post-mining context is also being considered (da Silva et al., 2022).

Soil bacteria can also produce a range of other surface-active agents or biosurfactants which aid in colonization of soil. For example, *Pseudomonas fluorescens* strain SBW25 produces the surfactant viscosin capable of altering local soil water distribution in soil microcosm experiments (Fechtner et al., 2011). It remains to be seen whether the beneficial properties of EPS- and surfactant-producing bacteria could be harnessed at large scale but given the increasing areas of cropping land impacted by drying conditions and salt stress, this approach warrants further attention.

The enhancement of the strength of soil through the activity of microorganisms or their by-products is a relatively new area of research known as biocementation. Urease-producing microorganisms such as *Sporosarcina pasteurii* were found to induce carbonate precipitation which improved the geotechnical properties of sand (Badiie et al., 2019). The studies referenced here hint at the potential for soil inoculants to be used to improve soil characteristics, including increased resistance to erosion, but much more proof is needed in this area.

Microbial consortia

Because of the highly complex nature of soil microbial communities and the diversity of niches available for colonization in soil, it is reasonable to expect that a mixture of compatible microorganisms with beneficial traits will enhance the likelihood of inoculated microorganisms establishing and persisting in different locations in soil. In addition, there is now ample evidence that microbial communities often work cooperatively to carry out specific functions. To date, most soil inoculants currently on the market contain a single inoculant strain but there is increasing evidence that better outcomes are achieved when multiple microorganisms are inoculated simultaneously. Co-inoculation of wheat seeds with the well-studied *Penicillium bilaiae* and a strain of *Bacillus simplex*, isolated from hyphae of *P. bilaiae* (and previously shown to stimulate *P. bilaiae* growth and P solubilization in the laboratory), increased plant P uptake from soil containing little available P above levels achieved with either inoculant alone (Hansen et al., 2020). Another field study examined the impact on growth of faba bean and wheat of inoculation with plant growth-promoting rhizobacteria (PGPR) alone; rhizobia alone; a mixture of PGPR and rhizobia; AMF alone; and mixture of PGPR, rhizobia and AMF. Inoculation with all three groups of microorganisms together resulted in significant improvement in crop biomass and improved the nutrient content of the crops, over that achieved without inoculation or the use of only single inoculants (Raklami et al., 2019).

Similar outcomes were found when soils were inoculated with a PGPR consortium of three strains effective against soil-borne disease of sweet pepper (Yang et al., 2014). Disease was suppressed, plant yield was increased, and improved soil nutrient levels were highly correlated with abundances of the inoculated species. These detailed studies are beginning to build the knowledge base needed to guide development of efficacious soil inoculant products based on consortia.

The studies described above used combinations of well-characterized microorganisms but many polymicrobial soil inoculants on the market today contain as many as 10 or more different microorganisms, sometimes with relatively low levels of each. Product claims are often very general such as “probiotic,” “living biostimulant,” “soil conditioner” and the mode of action of the consortium members are not well understood. It is unclear how the combinations of microorganisms brought together within such products have been selected and whether they do in fact work in unison or are competitive.

Developing a microbial consortium-based inoculum will involve selection of the desired strains, their ability to survive within a consortium and in the soil environment to confer the desired benefits in the field. Systematic approaches to development of multi-species inoculants that account for the specific properties and biocompatibility of the co-inoculant species are needed. While very laborious, deliberate design of a multi-species and AMF-biocompatible inoculant of phosphate rock (PR)-solubilizing bacteria yielded two effective combinations of co-inoculants that significantly enhanced maize biomass and uptake of N, P and K (Magallon-Servin et al., 2020), likely through the inclusion of P-solubilizing strains that utilized a range of different P-plant acquisition strategies. Similar outcomes with co-inoculation have been reported in other recent studies (Ribeiro et al., 2022).

Soil and environmental factors impact on inoculation

The heterogeneity of the soil as the receiving environment provides both opportunities and challenges for establishment and persistence of soil inoculants. Neutral pH, adequate moisture, adequate organic carbon, and low salinity favor microbial colonization, function and persistence and unfavorable soil conditions (such as pH extremes) are best managed prior to application unless the inoculant has been selected to operate under specific environmental conditions (Lopes et al., 2021). Impacts of pH have been reported for several inoculants including the P-solubilizing fungus *Penicillium* spp. where greater inoculation response was achieved in neutral and alkaline soils, while rhizobia inoculants vary widely in their ability to function in acidic soils (O’Callaghan et al., 2022). Soil salinity can also restrict microbial activity in soil, sometimes requiring the selection of salt tolerant inoculant strains. An example is a salt tolerant strain of *Sinorhizobium medicae* selected for successful nodulation of the pasture legume messina (*Melilotus siculus*) in saline soil, because of its improved survival over summer (Bonython et al., 2011).

For broad-acre crops grown in rain-fed agricultural systems, adequate soil moisture and temperature support use of soil inoculants, but in Mediterranean climates, conditions for microbial function may only be optimal around the time of crop establishment. However, some studies report better inoculation responses when plants are under environmental stress, such as in dryland agriculture (Schütz et al., 2018). Drying and wetting cycles in soil can be detrimental to microbial survival so inoculants are generally best introduced into the soil when moisture is adequate for seed germination. Microbes able to survive on seed in high numbers may have an advantage in these environments.

Knowledge of the soil nutrient status should guide use of inoculants as N-fixing and P solubilizing inoculants will likely decrease as levels of soil N and P increase. Mathematical modeling suggests that inoculation with PGPM is more efficient in nutrient poor soils, or stressed soils, because the development of the resident microflora is inhibited (Lopes et al., 2021). Other nutrient deficiencies may limit success of inoculants, for example molybdenum is important for N fixation by rhizobia and other elements may be important in microbial degradation of pesticides. It is important that deficiencies are addressed at time of application and interactions between elements must also be considered; inoculants intended to build soil organic C and improve soil structure will only be effective in the presence of sufficient soil N.

Competition between inoculants and resident soil microbial communities

After inoculation, cell numbers typically undergo a rapid decline, in part because of intense competition with the resident soil microbiome for niches and resources in soil, and predation by protozoa and nematodes. Soil microbial communities are highly complex and diverse and are typically resistant to invasion by applied microorganisms. In addition, the inoculant will almost always be numerically disadvantaged. For example, high quality peat inoculants will typically be applied at a field rate equivalent to 2.5×10^{10} rhizobia per ha, while naturalized soil communities of rhizobia often exceed 2.5×10^{12} rhizobia per ha. Placement of high numbers of inoculants very close to the roots to facilitate colonization of roots is therefore very important.

The presence of competitive microbes in the soil is less of a problem where host specificity is strongly expressed, where the function targeted by the inoculant microbe is specific rather than generic, or where the number of competitors has declined over time because the plant host is not consistently present, or soil conditions are unfavorable to the survival of the competing microflora.

Soil disturbances that disrupt microbial communities, such as tactical cultivation, may provide the opportunity to tip the balance in favor of inoculant microbes or reduce the impact of antagonists. Carefully designed formulations which provide the inoculant with a competitive edge, through provision of resources or safe niches within soil are also under investigation (see below). Such

tailored resource pulses may be able to disrupt the equilibrium within the resident soil microbial community and allow the inoculant to become established or proliferate.

Quality and delivery of soil inoculants

Standard production methods for inoculants utilize nutrient rich cultivation media and often produce cells that are sensitive to the abiotic and biotic conditions encountered in soil. Pre-conditioning cells to stresses encountered in the soil environment during production and formulation processes can enhance the ability of applied cells to survive and establish. Microbial inoculants require formulation to ensure acceptable shelf life prior to application, to enhance survival in the field, and to enable delivery of inoculants using common agricultural machinery. Peat-based formulations have been traditionally used for the delivery of soil inoculants. Peat provides a good niche for microbial growth when outside the soil and protection once applied. However, as peat is a non-renewable resource, new formulations are required utilizing cheap, abundant carriers; nevertheless, most alternatives tested to date have been considered inferior to peat (Bashan et al., 2014) and while synthetic formulations based on polymers and more recently nanomaterials have been proposed, raw materials for these formulations are expensive compared to peat and other organic matrices and have only been used experimentally to date. The shelf life of inoculants can be limiting compared to traditional agrichemicals and some inoculants require refrigeration until use. Upskilling of merchants and growers, accustomed to handling chemicals, to store and use biological products correctly, will be critical to ensure the success of inoculants in the field. Although inoculant formulations based on solid carriers, such as peat, generally have a shorter shelf life than those formulated as liquid products, which may contain additional nutrient and cell protectant compounds, solid formulations provide superior protection for the cells in the soil post application.

Most soil inoculants are applied early in plant development, usually at time of sowing in furrow as liquid or granules, on seed as slurry or as pre-coated seed treatments (Fig. 2). In-furrow application of inoculants is often successful but can be more expensive as large quantities of inoculant are required. Granules are increasingly used as they are convenient to apply, and correct placement and inoculant application rate are easily managed. Granules can also protect the inoculant from seed-applied fungicides and pesticides. Liquid formulations for in-furrow treatment are also popular with growers as they are easily handled but may not provide the inoculant with sufficient protection against unfavorable soil conditions since they lack the protection of a carrier such as peat and are more likely to be washed through the soil profile under irrigation or heavy rainfall.

Fig. 2 Commonly used formulations and application methods for soil inoculation.

Seed treatments have been used to deploy beneficial microbes for decades and they tend to deliver consistent results and are very cost effective (O'Callaghan, 2016). Seed inoculation typically requires less inoculant to be applied than other application methods, although (small) size of seed can limit the amount of inoculant applied. However, seed inoculation is far more challenging than coating of seed with agri-chemicals as the microorganisms must survive the environmental stresses of the seed treatment process, in particular high temperature and desiccation. In addition, incompatibility with fungicides and insecticides applied to seed can be detrimental to inoculant survival, and careful formulation may be required. These issues may be compounded where seed is pre-inoculated and stored, sometimes for months, before distribution to growers. Seed inoculation close to the time of sowing reduces this risk. There remains a need to find biomaterials and seed treatment processes that provide a microenvironment to protect microbes from desiccation while also having the mechanical properties needed to form a robust but functional layer around the seed. The inclusion of various secondary metabolites (flavonoids, phytohormones and nodulation factors) to formulations and seed treatments also shows promise in improving efficacy of inoculants. For example, the addition of small amounts of flavonoids to rhizobial formulations alleviates the effects of adverse conditions and enhances nitrogen fixation (Morel et al., 2016). Improved seed treatment processes are needed to ensure consistent loadings of functional mixtures of physiologically active and primed inoculants on seed that maximize seedling protection and vigor (Fig. 3).

In situations where application is required outside of the traditional in-furrow or seed treatment methods, such as inoculation of established pasture or into areas inaccessible to farm machinery, methods of application are limited. There are a few liquid formulations of soil inoculants on the market that are designed to be sprayed onto the soil or foliage. While there are several biological mechanisms that may assist the movement of inoculants through soil, the success of such applications is likely to be limited as microbes applied by spray will be subjected to desiccation and UV light and will to a lesser or greater extent rely on precipitation to move into the soil profile. Formulations designed to provide a protective environment enabling the survival of inoculants under adverse conditions that release when environmental conditions are optimal for inoculant movement have been described (Wright et al., 2017) and have potential for aerial application to inaccessible areas.

Field efficacy

Despite the potential demonstrated by many beneficial microorganisms, relatively few have been developed into commercially available products, and even fewer of these have been subjected to robust validation under a range of soil and environmental conditions. Field efficacy of microbial inoculants can vary widely across sites and climatic conditions, and inconsistent performance of some inoculant products is an ongoing science and industry challenge. However, it must be remembered that an inoculant will be beneficial only if it is targeting a significant limitation in the soil where it is applied. Products claiming improved nutrient availability will only be effective where a nutrient is lacking, in the same way that fertilizers provide benefit where specific nutrients are limiting. Similarly, use of an inoculant to control a soil-borne plant disease will only provide benefit where the targeted pathogen is present, and conditions are conducive to expression of disease. Agronomic decisions around use of inoculants should

Fig. 3 Future biological seed treatments may deliver multiple beneficial microorganisms and metabolites that work together to increase seed germination and plant establishment and yield.

mainly be based on prior knowledge and testing for soil constraints, as garnered from pre-testing soil fertility, or farmers observations of production-limiting populations of pests. Under some circumstances inoculant application can be justified on the basis that it provides insurance against infection and crop loss, so long as the cost is not prohibitive. Rhizobia (biofertilizer) inoculants are often used as an insurance policy when legumes are sown, because the cost of a crop failure can be large, relative to the small cost of inoculation.

Where scientifically validated products are used according to the manufacturer's instructions, significant increases in crop production have been reported, especially for inoculants used with legumes. Because legume inoculants have been used for many decades in association with a range of crops and under various soil and environmental conditions, robust meta-analyses of their efficacy can be undertaken, showing the important contribution of inoculants to global agriculture (e.g., Schütz et al., 2018).

Safety

Knowledge on the safety of soil inoculant products varies widely and has not been well studied for many products. Registration of inoculants as biopesticides usually requires submission of field trial data to support efficacy claims and evidence of mammalian and environmental safety, including lack of phytotoxicity and impact on key non-target species, such as earthworms, pollinators, and the indigenous soil microbial community. Users of biopesticidal inoculants can therefore have some confidence in the product claims as the data is often published in peer reviewed journals or independently evaluated as required by regulatory authorities. In contrast, inoculants described as biofertilizers, biostimulants and plant growth promoters have generally not been subjected to the same level of scrutiny in terms of their potential non-target effects.

Other factors to be considered in assessing the likelihood of non-target effects of inoculants include the establishment and extent of spread of microorganisms beyond the site of application. There are challenges in tracking applied strains within the complexity of the resident soil microbial community (Manfredini et al., 2021) and establishment and spread will be impacted by a multitude of environmental and biological factors, including the innate invasive capacity of the inoculant and its persistence under wide ranging field conditions. Research shows that many inoculants modify the soil microbial communities in various ways in the short or long term (Cornell et al., 2021). In some studies, the soil microbial community did not revert to its initial state after inoculation, even when the inoculant strain(s) had declined quickly following application. In contrast, other studies report only short-lived changes in the soil microbial community, that are minor in comparison with seasonal fluctuations. Mechanisms underpinning changes in the structure of soil microbial communities range from resource competition to direct antagonism and it is often not clear whether soil functions have also been impacted.

The deliberate introduction of microbial inoculants into new ecosystems is attracting increasing scrutiny, reflecting growing awareness of the need to protect indigenous soil microbial diversity, and increasing biosecurity concerns around movement of microorganisms across borders and the potential for widespread application of inoculants to trigger invasions by formerly non-invasive crops or co-occurring plants. Inoculant products containing large numbers of diverse, unnamed, and uncharacterized microorganisms is cause for concern, especially for soil inoculants intended for global markets, as the release of alien species poses a potential risk of disrupting integrity of indigenous communities. This is particularly true for inoculants composed of microbial consortia, because of the technical challenges and complexities of monitoring multiple microorganisms simultaneously in the environment.

Emerging approaches

Targeted design of microbial consortia

Microbial consortia are ubiquitous in soil and can outperform single microorganisms at multiple tasks. When used as inoculants, they have the potential to endure more changeable environments, as they may occupy a broader resource niche in soil together versus alone, allowing them to compete more effectively with resident soil microorganisms. In addition, the complexity of soil microbiome–plant interactions suggests that use of consortia may be a more useful strategy than using single microorganisms as inoculants. While inoculant products containing multiple species are available on the market, the rationale behind selection and collective performance of the consortia is often questionable. Several recent studies have demonstrated robust scientific approaches to selection and design microbial consortia capable of delivering greater benefits than single-species inoculant products. For example, Paredes et al. (2018) described a new method to design and predict the impact of novel bacterial combinations that modified phosphate accumulation in the plant shoot by constructing synthetic communities and testing their effects on plant phenotypes. Another approach—state-of-the-art metabolic modeling—was used to predict the efficiency of degradation of the herbicide atrazine by constructed microbial consortia, as well as the mechanisms underpinning herbicide inactivation. While not yet validated in field trials, this approach is another promising tool for consortia design (Faust, 2019).

Novel formulation and delivery systems

The spatial distributions of microbial populations across landscapes are highly variable and broadacre application of inoculants is expensive. Remote sensing and targeted application technologies currently in development for the precision application of pest and

disease controls, and nutrient management programs have potential as tools to enable the targeted application of soil inoculants, reducing the quantity of inoculant needed to achieve a response. Novel formulations that provide physical refuge for inoculants enable sustained, multiple invasions of inoculant into the local environment over a longer period than traditional formulations and improve the chances for establishment of inoculum in the environment.

Incorporation of growth substrates within a protective matrix allows multiplication of the inoculum in the environment after application and provides sustained delivery of inoculum. The introduction of inoculants via the seed microbiome using the seed as a protective carrier is a novel concept. This is achieved by spraying bacteria onto the flowers of crop plants to colonize the flower and subsequently become incorporated into the seed where they are protected from competition in the soil and rhizosphere and can colonize the developing plant at an early stage of development (Sessitch et al., 2019.) The feasibility of this approach has yet to be validated at scale.

Genetically modified microorganisms as inoculants

The potential use of genetically modified microorganisms (GMMs) as soil or plant inoculants has been proposed for decades but they have not yet seen practical use in the field. Advances in synthetic biology-based approaches is leading to generation of precisely engineered bacteria with additional beneficial functions. For example, inoculation of model experimental plant species *Arabidopsis thaliana* with transgenic bacterial strains engineered to over-express several phytase enzymes supported improved plant growth under phosphorus-limited conditions (Shulse et al., 2019). While these experiments were not conducted in soil, the approach can be considered a first proof-of-concept in development of effective phosphate-mining bacteria for future use in agriculture. However, while genetic modification of crops is widely accepted in agriculture, the use of GMMs has not yet become common practice. Further work on the stability and biosafety of engineered microbial inoculant species is needed.

Outlook

Progress is being made toward development of more reliable and well-defined soil inoculants, with use of some recent scientifically validated products being guided by detailed information on individual strains, their mode of action, and when and how to best store and apply the product. Deeper knowledge of the plant microbiomes of key agricultural crops and their interactions with the soil microbiome, in combination with detailed modeling is facilitating improved selection and development of microbial consortia with multiple functionalities capable of establishing under a range of geographical and environmental conditions.

Abstract

Plant diseases caused by soil-borne pathogens are a major limitation to crop production every year, and new tools are needed for more effective management. In this chapter, we argue for an expanded role for biological control, which involves the use of other living organisms to antagonize plant pathogens. Biological control approaches are complementary to our existing tools for managing soil-borne diseases, which include chemical pesticides, soil solarization, sanitation, crop rotation, and the use of genetically resistant crop varieties.

Key points

- Soil-borne diseases cause major economic losses in crop production.
- Management of soil-borne diseases is challenging because of pathogen survival and the difficulty of treating the whole soil volume.
- Soil harbors both detrimental and beneficial microbes; some of these microbes cause plant disease, while others constrain pathogen success.
- Disease control should not depend on a single strategy, because of off-target effects and the potential for pathogen evolution to circumvent that control.
- Biological control uses living organisms to reduce the impact of pests including soil-borne pathogens.
- Biological approaches are an attractive tool to complement traditional control strategies of soil-borne pathogens.

Introduction

Until the nineteenth century, many scientists believed that various plants are normally sterile and free from microbes within their tissues, as hypothesized by well-known scientists such as Pasteur and Chamberland. In the late 1800's, when Galippe reported that microbes from soil colonized interior parts of vegetable plants (Galippe, 1887), he was highly criticized by other scientists. By the early twentieth century, however, it had been established that many soil microorganisms can be harbored within internal plant tissues, and today it is well known that in both managed and natural ecosystems, a wide range of microbes colonize plant tissues. In fact, the mutualism of terrestrial plants with fungi has been found in fossilized tissues from 400 million years ago. Thus, the presence of microbes along with plants is now considered to be the rule, rather than an exception.

Among these microbes that associate with plants, soil-borne pathogens are a major threat to crop production. Common pathogenic genera include *Fusarium*, *Rhizoctonia*, *Sclerotinia*, *Verticillium*, *Pythium*, and *Phytophthora*. Yield failure resulting from soil-borne diseases such as seedling damping-off, root rot, stunting and wilting have destroyed entire agricultural industries. There is no country or geographic area without soil-borne disease problems, and some soil-borne diseases have been a serious problem for many decades and are responsible for restrictions on agricultural yield.

Management of soil-borne diseases in cropping systems is often highly challenging. In many cases, soil-borne diseases share similarities in symptoms, which makes the accurate diagnosis of a particular disease more difficult and subsequently harder to manage. Once established, soil-borne pathogens often survive for long periods in the soil, even in the absence of host plants. They

can survive either as saprotrophs or as living resting spores, which in the case of certain pathogens have the capacity to survive for at least 15 years waiting for a suitable host. Furthermore, the depth and complex structure of soil precludes the use of many of the tools that can be used to effectively control foliar diseases.

Managing soil-borne diseases presents a tremendous practical challenge, but the persistent nature of this problem also suggests the limitations of our understanding of mycology, bacteriology, nematology, genetics, molecular biology, ecology, and soil microbiology; with a sufficient understanding of these aspects of life in soil, surely effective management of soil-borne diseases would follow!

The objective of this chapter is to summarize the current practices for control of soil-borne diseases, with an emphasis on biological control approaches.

Soil-borne disease management

Integrated disease management draws tools from a diverse toolbox to effectively and economically respond to the particularities of each soil-borne disease scenario. Some of the most frequently used tools for preventing and managing soil-borne disease include chemical control technologies, soil solarization, sanitation, employment of crop rotations that promote the decline of pathogen populations, and the use of genetically resistant crop varieties. To this set of practices, biological control approaches offer unique opportunities and complementary mechanisms of control, and we advocate for expanded research and use of biological control for soil-borne diseases.

Chemical control

At an instinctive level, perhaps the most straightforward approach to managing soil-borne pathogens is to attempt to kill those pathogens prior to introducing a crop. However, in practice this impulse is exceptionally difficult to enact effectively; it is very challenging to expose the full soil volume to substances or conditions that would be lethal to pathogens, due to factors such as the depth and volume of soil, heterogeneity within soil, including discontinuities among patches of soil air and water, as well as chemical sorption phenomena and the potential for rapid biologically-mediated modification of bioactive compounds.

Nevertheless, chemical pesticides have been widely used to control soil-borne pathogens. These can be categorized according to their mode of application and intended zone of protection: chemical fumigants represent an attempt to eradicate a pathogen from the entire soil volume via exposure to toxic gases, while chemicals applied in the furrow or as seed coatings aim for narrower control of pathogens within the germination zone of the seed. Some foliar-applied pesticides may be taken up by the plant and translocated systemically, such that soil-borne pathogens in the rooting zone may be controlled.

One of the issues that accompany repeated use of chemical control technologies is the potential for the development within pathogen populations of resistance toward the action of a given chemical pesticide. In particular, broad use of pesticides that target a single biochemical step within the pathogen's cells can quickly select for resistance. There are thousands of polymorphisms within the genomes of soil-borne pathogens, and in large populations, rare genetic variants will likely exist that impact the efficacy of chemical pesticides. As a result of widespread pesticide use, lineages that are less sensitive to the effects of the pesticide will increase in frequency in response to selection, at the expense of more sensitive members of the population (Hollomon, 2015).

Environmental concerns represent a further downside of chemical pesticides; to the extent that these compounds contribute to ecological disturbance, human health hazards, and damage to aquatic ecosystems, their use in agriculture is problematic. For instance, chemical fumigation has been a major tool for soil disinfestation, yet fumigants are associated with harmful side effects, such as environmental pollution and ozone depletion (Mihajlović et al., 2017). The safe and effective use of soil fumigants requires consideration of site conditions (soil, air, weather), buffer zone establishment, emergency response planning, and most importantly, sealing the soil surface immediately after injection of the fumigant, usually with impermeable film, which adds to the capital and labor expense. In many parts of world, the fumigant methyl bromide was extensively used to control soil-borne diseases before the implementation of the Montreal Protocol in 1992 (Mihajlović et al., 2017). In recent years, progressive restrictions on the use of methyl bromide, because of its contribution to thinning of the ozone layer, have brought into sharp focus the need for alternative strategies for the management of soil-borne diseases.

Solarization

An innovative approach to removing pathogens without the application of toxic chemicals is to use soil solarization. Soil solarization, introduced by Katan (1981), involves management practices such as the deployment of plastic tarpaulins under very sunny conditions to elevate soil temperature by 2 to 15 °C above the ambient temperature of untreated soil. This heating has a profound impact on soil microbial communities, and can cause the death of plant pathogens, especially those that cannot endure temperature above 37–40 °C. Similarly, the seedbank of weed seeds, as well as various insect and nematode pests, can be rendered non-viable through soil solarization.

However, the efficacy of soil solarization declines with soil depth, and many agricultural regions do not have suitable environmental conditions for effective solarization. Furthermore, solarization approaches share with chemical fumigants the issue of leaving the post-treatment soil 'wide open' for rapid spread of new colonists; if pathogens are among the first microbes

to re-establish after treatment, they may experience an environment of low competition, enabling their rapid proliferation and spread. One promising approach may be to couple soil solarization with the immediate application of beneficial microorganisms, such that the establishment of beneficial organisms is promoted in the less competitive environment immediately following solarization, erecting a barrier toward the re-establishment of pathogens.

Sanitation

An approach that aims to prevent the introduction of pathogen propagules to soil, and to remove resources and refugia that promote pathogen survival or reproduction, is complementary to strategies for actively destroying pathogen populations. A key aspect of this approach is to maintain sanitation. Most soil-borne diseases are caused by eukaryotic pathogens that are able to produce resting structures like chlamydospores, microsclerotia, oospores or sclerotia. Furthermore, many of these pathogens also subsist on crop debris as saprotrophs. Therefore, preventative sanitation practices can be seen as attempting to avoid a disease problem before it becomes severe. Examples of sanitation include removing infected plant material, as well as cleaning the tools and equipment that are used in the field, and limiting transfer of soil among fields. Tillage and residue management, such as harvesting, burning, or chopping residue, have been used to accelerate the displacement of pathogens from infected crop debris. These practices may expose the debris to conditions that are less favorable for the pathogen or may accelerate processes of decomposition. Somewhat related are practices that aim to reduce susceptibility to disease by adjusting environmental conditions to be close to the optimum for a given crop species, such as through pH adjustment, provision of adequate nutrition, or moisture management. Here, the goal is preventative; by enhancing plant vigor and limiting pathogen success in the present, fewer epidemics of soil-borne disease are expected in the future.

Despite its benefits, sanitation alone is frequently insufficient to prevent disease outbreaks. In the contemporary context, there are also increasingly competing pressures from additional expectations being brought to agriculture. For instance, society is increasingly coming to expect that our agricultural soils will hold large amounts of carbon (i.e., as one of our strategies for mitigating the rise in atmospheric carbon dioxide concentration). Managing for high soil carbon is frequently at odds with managing for sanitation and removal of pathogen refugia.

Crop rotation

One effective strategy for steering pathogen populations into decline is to rotate the plant cover over an entire field to a very different plant species from 1 year to the next. Indeed, rotating among crops has been used for hundreds of years to promote productivity, even if the specific mechanisms were not understood in detail. Crop rotations have a marked effect on the incidence and severity of soil-borne disease, by avoiding the buildup of inoculum in soil. Under a scenario of repeated monoculture, cultivating the same crop species in a field year after year, pathogen inoculum can become progressively more abundant. There are also mechanisms by which diversifying crop rotations can have beneficial impacts on soil structure and fertility, as well as control of weeds (Reddy, 2017). For effective control of soil-borne pathogens, crop rotation typically aims for a sequence of very dissimilar crops, such as switching between plant families. For example, rotation with a legume is an effective approach for management of fusarium wilt in tomato. The concept is that the more widely divergent the plant species are, the less likely it is that they will share pathogens.

Despite its apparent simplicity and power, crop rotation has limited efficacy in the case of some soil-borne diseases, notably those caused by pathogens with a wide range of host plants, and those caused by pathogens with exceptionally long-lived survival structures like sclerotia, oospores or chlamydospores. For pathogens with a very wide host range, it may be difficult to find non-host plants that can be economically produced. For pathogens with exceptional longevity, the rotation system that would be needed to effectively drive down pathogen population density may be prohibitively long; for instance, in some cases it may be necessary to rotate away from the host crop for 5 years or longer. With such an infrequent return interval, it may be challenging to maintain the equipment necessary for a particular crop, and investment in regional-scale infrastructure, such as processing facilities, may also be disincentivized because of the limitation imposed on the acreage available to a particular crop. Some pathogens, such as *Sclerotinia sclerotiorum*, combine both challenges in that they have a broad host range as well as produce resilient survival structures (Liang and Rollins, 2018), making these pathogens particularly difficult to manage via rotation alone.

In addition to rotating between main crop species from 1 year to the next, there are also practices that increase plant diversity over time by adding plant species from which no harvest is intended. Such plantings are referred to as cover crops, and may be inserted into rotations during periods of the year that are not sufficient for growth of a harvestable crop. Cover crops are intended to provide services and benefits other than harvested grain. Displacement or control of pathogens may be one of the services that are available from cover crops. However, care should be taken, as it is also possible that cover crops could serve as hosts or refugia for pathogens, limiting the efficacy of rotations. For example, the common cover crop winter cereal rye hosts multiple pathogens capable of also infecting a subsequent corn crop (Bakker et al., 2016); thus, farmers have to select crops for rotation very deliberately and empirical testing of performance is critical.

Resistant varieties

Developing crop varieties that have genetic resistance toward pathogens is complementary with all other control strategies, and is unparalleled in terms of its efficacy and cost effectiveness. For instance, crown and root rot of sugar beet (*Beta vulgaris*) caused by

Rhizoctonia solani can be controlled to a large extent by selecting highly resistant cultivars. The beauty of resistant varieties is that they can obviate the need for other inputs or management practices that may add to the cost of production or produce undesirable side effects. Where particular genes have a large impact on resistance or susceptibility, and where genetic markers are available, plant breeders can very rapidly improve the genetic resistance of crops toward certain pathogens. In some cases, genetic modification has been used to engineer resistance toward plant disease. Most famously, a transgenic approach saved the papaya industry in Hawaii from being rendered untenable by a ringspot virus. With respect to soil-borne diseases, traits related to root exudation may be particularly relevant to interactions with pathogens. In one case, root exudates of a resistant tobacco cultivar showed inhibitory activity against the pathogen *Phytophthora nicotinae*, whereas the exudates of a susceptible cultivar stimulated growth of the pathogen (Zhang et al., 2020). Much more research is needed to understand in detail how root exudation could be modified during cultivar development and the extent to which related traits may be selected upon to improve resistance toward soil-borne pathogens.

There are several clever ways to multiply the benefits of genetic resistance via management decisions. One of these approaches involves growing cultivar mixtures, in which a resistant cultivar is paired with one or more other varieties, which may lack resistance or may possess a different resistance profile. For example, compared to growth in a pure stand, a wheat cultivar that is susceptible to soil-borne wheat mosaic virus (which is vectored by nematodes in soil) demonstrated lower incidence of infection when grown in a mixture with a resistant cultivar (Hariri et al., 2001). In these cultivar mixtures, the development and spread of disease can be slowed through epidemiological mechanisms (Mundt, 2002). However, the efficacy of this approach is dependent on the life cycle of the pathogen, host specificity, and spatial distributions of both the pathogen in the soil and of the crop cultivars.

Grafting is a second technique that maximizes the utility of genetic resistance. This technique is popular in fruit trees as well as in high-value vegetable crops such as peppers and tomatoes, where it is used increasingly to manage the Verticillium wilt (Mackey et al., 2018). Some bacterial wilt and root knot nematodes of vegetables are also managed by grafting techniques. The advantage of this technique is that it permits separate consideration of desirable root traits vs. yield or quality traits of the portion of the plant that is actually harvested. In particular, the rootstock can be selected for effective resistance to soil-borne disease, without the need to consider potential impacts on traits of the aboveground portion of the plant. Although grafting can be done in a moderately high throughput fashion, this technique is limited by high costs and the need to transplant grafted seedlings; it is thus not applicable to most commodity crops.

Despite genetic resistance being a fantastic tool for management of soil-borne diseases, there are also some limitations and drawbacks to this tool. In similar fashion to the use of chemical pesticides, the largescale deployment of genetic resistance can exert substantial directional selection on pathogen populations, driving evolution of pathogen strains that are able to overcome the mechanism of resistance. Thus, vigilance is required to recognize new pathotypes and to improve genetic resistance. If resistance genes are deployed in a careless or uncontrolled manner, they may quickly fail; this represents a tremendous waste of what may be an irreplaceable resource. For some soil-borne pathogens, genetic resistance depends not on a few genes of large effect, but on many genes that each have only small effects; in these cases, progress in improving resistance is very slow and genetic resistance may not be available or adequate. Furthermore, there are some resistant cultivars that may be unacceptable due to other horticultural characteristics or insufficient quality traits.

Biological control

Complementary to all previously discussed methods for controlling soil-borne disease, is biological control: the use of another living organism for the control of a pathogen. Soil sanitation and solarization, crop rotation, breeding for new resistant varieties and grafting, and chemical pesticides are insufficient to control soil-borne disease in many agricultural systems. An increasing number of recent studies demonstrate that many fungi and bacteria can serve as antagonists of pathogens. These microbes associate with roots and can protect their host plants against soil-borne diseases. There is now substantial evidence that some beneficial microbes, particularly endophytic fungi and bacteria, are recruited by plants and these microbes can act as a second, microbiological layer for plant defense against biotic stresses (Dini-Andreote, 2020).

The biocontrol of soil-borne diseases via the application of living microorganisms has been researched for more than 80 years. In 1963, butt rot of pines, a disease caused by the fungus *Heterobasidion annosum*, was controlled by inoculation with a non-pathogenic fungus, *Phlebiopsis gigantea*. Successful biocontrol agents have been found in diverse microbial taxa, including fungi, bacteria, viruses, and protozoa. Some of these microbes have suppressive effects toward selected soil-borne diseases and also contribute to the success of plant defense strategies under greenhouse and field conditions.

Frequently, the goal with biological control, as for several of the control strategies discussed earlier, is not to eradicate a pathogen from the soil, but more modestly, to provide a barrier between susceptible plant tissues and the attacking pathogen. As a result, biocontrol agents that are able to colonize plant tissues either epiphytically or endophytically have been viewed as particularly attractive. Endophytic colonization refers to microbial growth within internal plant tissues that causes no apparent adverse symptoms. For instance, endophytic colonization of wheat by *Sarocladium zeae* successfully slowed the spread of the pathogen *Fusarium graminearum* through wheat tissue (Kemp et al., 2020). In addition, microbial associates of plants have many other functional roles, such as being plant growth promoters, protectors against plant herbivores, and aiding in nutrient acquisition. Thus, using biological control agents, especially those that colonize internal tissues of their host plant, is increasingly capturing the imagination of many microbiologists and plant pathologists.

Biological control agents currently in use

Many of the effective biological control technologies that have been developed are formulations of live fungi. Fungi play a functional role in habitat adaptation and enhanced plant resistance to both biotic and abiotic stresses because they are an important element of the microbiota of agricultural and forest ecosystems. In terms of taxonomic classification, a wide range of fungi inhibit the growth of soil-borne plant pathogens; more than 30 genera and 80 species of soil fungi (such as *Botrytis cinerea*, *Penicillium chrysogenum*, *P. citrinum*, *Gliocladium virens*, *Trichoderma glaucum*, *T. harzianum*, *T. koningii* and *T. viride*) have demonstrated antagonistic activity against soil-borne diseases in addition to their well-known plant growth promotion and enhancement (Tariq et al., 2020). A lengthier summary of fungal taxa that have been used in biocontrol is provided in Table 1. Non-pathogenic strains of *Fusarium* can live in soil, in the rhizosphere and in planta and show antagonistic activities against fungal plant pathogens. Other isolates such as some belonging to *Aspergillus*, *Saccharomyces*, and *Gliocladium* have shown great promise to inhibit and suppress the activity of pathogens such as *Alternaria*, *Aspergillus*, *Fusarium*, *Rhizoctonia*, *Pythium*, and *Phytophthora*. In addition to these genera, *Trichoderma* spp. have received a lot of research attention and have been developed into effective microbial biocontrol technologies that significantly reduce the incidence and severity of soil-borne diseases.

Under certain circumstances within an integrated pest management approach, some fungi that feed on nematodes can be used for biocontrol. Nematophagous fungi, like *Arthrobotrys*, *Dactylella*, *Dactylaria*, are used to trap root-knot nematodes, and a talc-based formulation of *Paecilomyces lilacinus* has been used for the control of plant-parasitic nematodes, as this fungus can parasitize nematode eggs (Pendse et al., 2013). Arbuscular mycorrhizal fungi have also been reported to reduce severity of many soil-borne diseases, including root-knot nematodes, although in some of these interactions, the antagonistic mechanisms and relevant functions are still unknown.

Microbes that colonize internal plant tissues (endophytes) are promising biocontrol agents because of the potential of this growth habit for close interactions with the plant, the increased likelihood that the biocontrol agent is present at the site of pathogen attack, and because a less competitive environment inside the plant (relative to the open soil) may facilitate longer persistence of the biocontrol agent. Fungal endophytes such as *Heteroconium chaetospora* and *Acremonium alternatum* have potential to be effective biocontrol agents against clubroot, caused by *Plasmodiophora brassicae* (Khalid et al., 2022). Frequently, close relatives of pathogens are found to be effective at colonizing plants endophytically. This adds some difficulty to the search for beneficial endophytes, as the close taxonomic affiliation to pathogens can raise regulatory hurdles or otherwise give pause. For instance, nonpathogenic *Fusarium* species can colonize internal plant tissues endophytically (Al-Ani, 2019), but *Fusarium* is best known as a genus containing many damaging plant pathogens.

It is particularly attractive to consider that some biocontrol agents may be able to bring multiple services to the crop production environment. Notably, various genera of entomopathogenic fungi (that is, fungi which parasitize or feed on insects) have been also shown to act as endophytes in plant hosts (Quesada Moraga, 2020) and demonstrate antagonistic activity against soil-borne pathogens. This dual action suggests that one biocontrol technology may be useful in providing protection against soil-borne diseases, and also against insect pests. Several strains with relatively broad host ranges have been developed into crop protection technologies, the majority based on filamentous Ascomycota within the genera *Beauveria* and *Metarhizium* (Clavicipitaceae) (Rasool et al., 2020). Many of these products have demonstrated antagonistic activities against soil-borne pathogens. For instance, *B. bassiana* strain ATCC 74040, applied on squash, has been reported to significantly suppress the incidence and severity of the zucchini yellow mosaic virus. Both *Beauveria* spp. and *Metarhizium* spp. play an important role in habitat adaptation of many species of host plants, resulting in improved plant performance.

Table 1 Fungal taxa reported as biocontrol agents against fungi and oomycetes causing soil-borne plant diseases.

Biocontrol agent	Test plant	Target pathogen
<i>Aspergillus fumigatus</i>	cocoa	<i>Phytophthora palmivora</i>
<i>Beauveria bassiana</i>	broad bean	<i>Botrytis cinerea</i>
<i>Beauveria bassiana</i>	grapevine	<i>Plasmopara viticola</i>
<i>Beauveria bassiana</i>	tomato	<i>Pythium myriotylum</i>
<i>Cladosporium</i> spp.	notoginseng	<i>Fusarium solani</i>
<i>Fusarium oxysporum</i>	soybean	<i>Sclerotinia sclerotiorum</i>
<i>Metarhizium anisopliae</i>	maize	<i>Fusarium graminearum</i>
<i>Trichoderma afroharzianum</i>	cucumber	<i>Sclerotinia sclerotiorum</i>
<i>Trichoderma asperellum</i>	thale cress	<i>Verticillium dahliae</i>
<i>Trichoderma atroviride</i>	beans	<i>Botrytis cinerea</i>
<i>Trichoderma gamsii</i>	rice	<i>Phoma herbarum</i>
<i>Trichoderma hamatum</i>	thale cress	<i>Phytophthora nicotianae</i>
<i>Trichoderma hamatum</i>	cabbage	<i>Sclerotinia sclerotiorum</i>
<i>Trichoderma harzianum</i>	rice	<i>Bipolaris oryzae</i>
<i>Trichoderma harzianum</i>	soybean	<i>Sclerotinia sclerotiorum</i>
<i>Trichoderma harzianum</i>	melon	<i>Fusarium oxysporum</i>
<i>Trichoderma virens</i>	tobacco	<i>Rhizoctonia solani</i>
<i>Trichoderma</i> spp.	avocado	<i>Rosellinia necatrix</i>
<i>Trichoderma</i> spp.	peanut	<i>Fusarium solani</i>

A major constraint to the development of biocontrol technologies lies in the requirements for stable formulation and long shelf-life under minimally controlled environmental conditions. These factors are often not given consideration in early research, which may explain why there is a much longer list of taxa that have shown early signs of being effective biocontrol agents, but a much narrower list of taxa that have been successfully developed into commercial products. For instance, bacterial biocontrol products are dominated by species of *Bacillus*, which are able to produce exceptionally robust spores.

Mechanisms contributing to biological control

Although a wide range of taxa have been shown to be capable of providing biological control over soil-borne plant pathogens, there are only a handful of distinct mechanisms underlying the provision of this service. These mechanisms can be fit into categories of resource competition, interference competition, and impacts on the susceptibility of the host plant.

Resource competition in biological control includes scenarios in which the beneficial strain occupies a niche that overlaps with that of the pathogen, such that the two organisms attempt to exploit the same resources, or to colonize the same physical spaces. Presumably, this competition will occur primarily prior to the pathogen's attack on the plant, although in the case of endophytic biocontrol strains, resource competition may take place in planta. The rhizosphere, the zone of soil immediately surrounding plant roots and under their heavy influence, is a site of intense competition. Because of the importance of this zone within soil, biocontrol strains are commonly evaluated for their rhizosphere competence, or the ability to colonize the rhizosphere at high densities and to persist over time in this environment. As an example of this category of biological control, the presence of endophytic fungi in the root of potatoes reduces incidence of *Rhizoctonia solani*, likely as a result of competition for ecological niche.

Interference competition refers to direct interactions between a biocontrol agent and the pathogen. For example, fungi such as *Acremonium alternatum*, *Acrodonitum crateriforme* and *Cladosporium oxysporum* can physically interact with and destroy the mycelia of plant pathogens. Antibiosis, or the release of compounds which are toxic to other microorganisms, is a common trait among biocontrol strains (Tariq et al., 2020). These toxins are typically secondary metabolites, a term which indicates that they are not essential to the basic cellular functioning of the organism. As 'accessory' functions, the ability to produce such metabolites can vary widely among strains and is not typically a conserved or reliable trait in a taxonomic sense. This functional variability motivates efforts to screen very large numbers of potential biocontrol strains to identify those rare strains that may either produce novel metabolites or produce prodigious quantities of some known metabolite of interest. Numerous studies have indicated that several established fungi in plants produce antibiotic and toxic compounds such as monoterpenes and sesquiterpenes to compete with soil-borne pathogenic organisms. Thus, specific compounds produced by *Trichoderma harzianum*, like harzianolide, 8-dihydroxy-3-methyl-anthraquinone, and azaphilones, inhibit the growth of *Phytophthora cinnamomi* as well as suppress the incidence of diseases caused by *Botrytis cinerea*, *Rhizoctonia solani* (Vinale et al., 2009), and *Pythium ultimum* (Tariq et al., 2020). The production of the antibiotic beauvericin by the fungus *B. bassiana* has a significant bioactivity and can inhibit the development of damping-off caused by *R. solani* and *P. myriotylum* in tomato and cotton (Jaber and Ownley, 2018). A cautionary note seems warranted: interference competition is a concept borrowed from traditional ecology, but whether microbial interactions are direct or 'intentionally' oriented toward a particular competitor is much more ambiguous. For instance, control of plant pathogens via antibiotic compounds produced by *Streptomyces* bacteria may be largely a side effect of, or damage collateral to interference competition among saprotrophic *Streptomyces* strains (Kinkel et al., 2012).

Finally, suppression of soil-borne disease development may arise through functions of a biocontrol strain that serve to enhance plant health or vigor. Microbial processes that are involved in plant growth enhancement can include production of phytohormones, altering the growth pattern of the plant, or increased provision of scarce nutrients like iron (e.g., via production of microbial siderophores, which are iron-chelating compounds that can be taken up from the soil solution together with their cargo of iron) or nitrogen (via fixation from atmospheric N₂) (Vessey, 2003). In each case, the effect relies on more vigorous plants being able to mount a more effective defense against pathogen attack. Plant growth promoting interactions are very complex to untangle as there are typically numerous confounded effects and feedbacks are likely. For instance, if interactions with a microbial partner alter root traits such as root hair density, root hair length, branching pattern, and so on, then there will be knock-on effects in terms of water and nutrient availability that are only indirectly associated with the action of the microbial partner.

Root colonization of soybean plants with *M. anisopliae* has been shown to produce greater amounts of jasmonic acid, increasing shoot length in comparison with fungal-free control. Some endophytic fungi, like *Aspergillus fumigatus* and *Fusarium proliferatum*, can produce phytohormones such as gibberellins, and thus, may alleviate some harmful effects of biotic stresses. The gibberellins and tetracyclic diterpenoid acid compounds, the most valuable group of hormones, are well known to contribute to plant development and regulate cell division. They benefit plants in different ways such as growth promotion, improvement in crop productivity and vegetative fitness, stem and leaf growth, floral initiation, and flower and fruit growth (Bilal et al., 2018). Furthermore, plant growth promotion by beneficial fungi also has been reported due to production of indole-3-acetic acid (IAA), which promotes plant root growth, root hair development, and is indispensable for plant growth and development.

Exposure to other microbes prior to pathogen attack, including beneficial microbes that may be deliberately applied, also has an impact on the speed and magnitude with which plants are able to mount their innate defense responses. This effect has been termed 'defense priming' (Conrath et al., 2015). There is, however, some uncertainty about the extent to which this effect may be an artifact of simplified experimental conditions during research, as most plants grown in a field setting are continually exposed to a wide range of microorganisms. Related concepts, which reflect the capacity of plants to respond with enhanced resistance within tissues that are spatially distant from the stimulus, have been termed systemic acquired resistance and induced systemic resistance (Vlot et al., 2021). In a regulatory context, products developed around microorganisms that interact primarily with the plant may be administered according to different rules (i.e., for 'plant growth promotion' products, rather than for 'disease control' products).

Microbiome management for biological control

Efforts to isolate and identify potential biocontrol strains have sometimes been successful by prospecting in areas with pronounced disease development, but an alternate strategy seeks to identify biocontrol strains in areas where disease fails to develop as expected (that is, in disease-suppressive soils). In the disease-suppressive soils that have been most carefully studied, pathogen control has sometimes been attributed to particular members of the soil microbial community, or even to particular secondary metabolites produced by certain members of the soil microbial community (Mendes et al., 2011).

The identification and study of disease suppressive soils that have arisen in various places and cropping systems has also given rise to a new aim for biocontrol: management of indigenous microbial communities to foster traits or community members that suppress pathogens, rather than inoculation with an exogenous strain to introduce this function. Management practices that could conceivably be used in service of microbiome management aims include crop rotation, crop genotype selection, amendments of various types, and perhaps even targeted disruption events.

Plant root-associated microbiomes, such as rhizosphere and the endospheric microbial community of roots, are considered as a critical factor for understanding the interactions between plants and soil. Root-associated microbes are recruited from the soil, and many provide benefits for the host plant, such as facilitating nutrient availability. Endophytic microbes have an interspecific interaction with their host plants for a portion of or their entire lifecycle and cause no apparent adverse symptoms. Numerous studies have shown microorganisms such as bacteria and fungi have been successfully adopting a lifestyle as endophytes by colonizing plant tissues in many crop plants such as potato, broad bean, maize, cotton, wheat, tomato and oil seed rape. There have been demonstrations of colonization by endophytes leading to significant alleviation of abiotic stress, as for example due to salinity (Gupta et al., 2021).

Outlook

There is an on-going need for improved technologies to control soil-borne plant diseases, as made clear by persistent losses to soil borne-disease, together with off-target effects of conventional management practices and the rise of goals for agriculture that go beyond food production. Furthermore, relying on a single strategy to combat the threats posed by soil-borne diseases is not an effective solution over the long term. On the other hand, non-chemical options such as soil sanitization and solarization, crop rotation, using resistant varieties, and microbial biological control agents may not satisfy growers' expectations. However, applying all these tools together as an integrated system can hold the population of soil-borne pathogens below the economic threshold level and in an environmentally friendly way without imposing adverse impacts on the fauna and flora of the agricultural system (Fig. 1).

Fig. 1 Overview of tools that can be used in the integrated management of soilborne diseases, including biological control approaches. Pathogens should be understood as members of the soil microbiome, able to be influenced through management of diverse aspects of the abiotic environment and of the community of interaction partners.

Abstract

A vast number and types of microorganisms occur in soil. They perform a wide array of processes and fulfil numerous functions, ranging from biogeochemical cycling to plant protection. The complexity of habitats and ecosystems in which microorganisms operate and the level of current understanding greatly limit our ability to manage them. One possible approach is to apply inocula of 'laboratory-grown' organisms that can complete missing or inadequate processes; however, its universal effectiveness poses considerable challenges. Alternatively, agronomic practices are selected, based on tillage and cropping systems, that are conducive to enhanced functioning of indigenous microbes against biotic and abiotic stresses.

Glossary

1-aminocyclopropane-1-carboxylic acid (ACC) 1-Aminocyclopropane-1-carboxylic acid (ACC) deaminase is an enzyme that degrades ACC, the precursor of ethylene, a gaseous plant hormone present in all higher plants. Numerous bacteria, which can enhance plant growth, produce ACC-deaminase.

Operational taxonomic unit (OTU) Operational taxonomic unit (OTU), is the basic taxonomic unit identified by numerical genome analysis following high-throughput sequencing, and are so called because the units prescribed are not always comparable to those established by formal taxonomy. The information used is restricted to the nucleotide sequence of specific regions of DNA or RNA prepared by polymerase chain reaction (PCR), which contain copying errors at varying frequencies that depend on the techniques employed. A commonly accepted value for the variability within an OTU is 3%, resulting in its members sharing 97% similarity in base sequences. Numerical analysis tools are used to distinguish biological variations in sequences from those resulting from experimental copying errors. The OTUs that have gone through this 'denoising' process are referred to as zero radius OTUs or zOTU in short.

Key points

- Soil contains a large number of microbes, with bacteria ($\sim 10^8 \text{ g}^{-1}$), algae ($\sim 10^6 \text{ g}^{-1}$) archaea (10^5 g^{-1}), fungi (10^5 g^{-1}), protozoa ($\sim 10^4 \text{ g}^{-1}$) and small-size animals such as nematodes ($\sim 10^4 \text{ g}^{-1}$) contributing the majority of individuals.
- These organisms contribute to a wide array of processes in soil that affect the growth and development of the plants and animals that inhabit each locality, as well as contributing to the major geochemical cycles.
- Given the numbers, types and activities of these microbes, and the ecosystems involved, coupled with the confines of current knowledge, our ability to manage them is very restricted.
- One approach is to apply an inoculum of organisms grown under controlled conditions to the soil, but such microbes may not be able to compete with the indigenous population or edaphic conditions might be sub-optimal. The alternative is to use agronomic practices that are conducive to the growth of indigenous microbes.
- A strategy for the deliberate manipulation of the indigenous arbuscular mycorrhizal fungi (AMF) population and its functional diversity. It requires the intentional use of selected host plants to form an extensive extraradical mycelium (ERM) involving a consortium of indigenous AMF.

Introduction

Over the last 30 years, the consequences for global climate change of the rapidly increasing greenhouse gas composition of the atmosphere coupled with the demand for food, fuel and fiber from an inexorably growing human population have highlighted key issues in agricultural production. These issues can be summarized as availability of land, water and essential inputs to ensure sustainable utilization of the other two resources. The area of land available for arable crops is declining because of urban expansion and soil degradation. Changes in the distribution of precipitation have exposed more crops to drought. Inadequate through drainage can result in the build-up of fertilizer residues and allow saline groundwater to enter the root zone. Constraints have been made to inputs of fertilizer and other agrochemicals to protect the wider environment and reduce greenhouse gas emissions, but this can also provide opportunities for altered ranges for plant pests and diseases.

The biological component of soil is critical for the breakdown of plant residues and their incorporation into soil organic matter (SOM). Soil fauna, including earthworms, collembola and mites, shred animal and plant remains to make them more accessible to chemical degradation by microbes, that operate the ultimate steps of mineralization. Microorganisms also have great potential to protect agro-ecosystems from stressors because of their ability (i) to improve soil structure by releasing mucilage that can stabilize soil particles into aggregates; (ii) to increase the availability of plant nutrients; (iii) to form different kinds of symbioses that enhance the growth of plants and protect them against different stresses. The current challenge is therefore, to establish and implement the criteria by which the beneficial functions of soil biology can be supported or even enhanced through agronomic practices that ensure sustainable food security. It also means maintaining or increasing microbial biodiversity to optimize the potential to counter biotic stressors, including pathogens and herbivores, and abiotic stresses, such as deficiencies or toxicity of mineral nutrients. In part that requires maintaining functional activity of microbes in the rhizosphere of plants, including endosymbionts. Biofilms appear to be an important mechanism by which microbes maintain their activity in soil, so limiting actions that can disrupt them is another prerequisite.

Major biological components of the soil that positively influence plant growth

The development of new generation molecular methods has greatly changed our knowledge of the organisms present in the soil. The genetic and functional diversity, positions in the 'tree of life,' inter-relationships, interactions and contributions to ecosystem functioning are, in some aspects, becoming clearer, but it also has extended the perception of what is yet unknown. Numbers of organisms are vast (Table 1), for example the total number of bacteria and archaea in the soil worldwide is estimated to be $\sim 3 \times 10^{29}$ cells; many can be detrimental to plants. The root systems of plants create a localized zone of influence by their extension, radial expansion, uptake of water and selective uptake of nutrients, release of exudates, and loss of cells. Organic material entering the soil as plant litter, harvest residues and rhizodeposition is decomposed by soil organisms, which use it as an energy source but can also add additional material, particularly their necromass. The rhizobiome is also important to the biogeochemical cycling of carbon, particularly in the turnover of the component present in the soil. Roots and the microbes of their rhizobiome determine the structure and stability of the rhizosphere at the same time as influencing the carbon cycle and the interactions among them. Within the species of the archaea, bacteria and fungi found in the rhizobiome, strains have been isolated that can greatly enhance the availability of mineral nutrients, or stimulate the extension of roots, act as biocontrol agents against pathogens and support plant dry matter production (Table 2). The host plant genotype is important in the formation of this rhizobiome (Fig. 1).

Table 1 The concentration of main groups of microbes, including nematodes in soil.

Organisms		Number	Units
Archaea		$0.2\text{--}0.4 \times 10^5$	amoA gene copies ^a g ⁻¹ × 10 ³
Bacteria^b		$4.4\text{--}29.1 \times 10^5$	cfu g ⁻¹ × 10 ³

Omnivores		0.22	g ⁻¹ × 10 ³

^aAssumes there are between 1 and 3 amoA (ammonia monooxygenase) gene copies per archaeal cell.

^bAssumes that less than 0.1 to 10% of total bacteria are culturable.

^cCounts of autotrophic microbes in the soil's crust (1 cm depth samples).

Given the wide range of soil organisms and the significance of the functions they carry out, there are obvious challenges to any attempt at directing their collective activities.

A definition of management in the context of soil microbes

Overall, soil and plant management strategies must maintain genetic and functional diversity by preventing the main causes of land degradation (Table 3). With our current knowledge, management of the microbial component of a soil has to depend on modifying the factors that determine the particular microorganisms present and those that influence their activities. Importantly, there is clearly a need to ensure that changes in the population of microbes do not adversely impact the range of functions that they perform. Equally, requirement for functional diversity must allow for sufficient genetic diversity. Activities of microbes are very dependent on temperature, the supply and quality of organic matter, mineral nutrients and the availability of water and oxygen.

Potential approaches to soil microbe management

Approaches to changing the composition of the microbe population involve addition of a specific inoculum or modifying conditions to stimulate components of the soil microbiome.

Inoculation

Techniques and opportunities for inoculation are discussed by Lopes et al. (2021) and O'Callaghan et al. (2022).

Inoculation of rhizobia

Rhizobia are commonly applied in agriculture to give improved nitrogen fixation in root nodules of pulse crops as well as other grain, fodder and pasture legumes (Fabaceae) relative to indigenous microbes. The competitiveness of an inoculant has to exceed

Table 2 Rhizosphere microorganism groups that have strains reported to promote growth and some processes by which it is achieved.

Domain	Phylum (Class)	Order (Family)	Example species	Nutrient availability				Effect on Plant or other microbes

Fig. 1 Diagrammatic representation of the major genera of indigenous arbuscular mycorrhizal fungi recruited into the rhizobiome of four plant species (wheat - L.; annual ryegrass – *Lolium rigidum* L.; yellow serradella – *Ornithopus compressus* L. and subterranean clover – *Trifolium subterraneum* L.) grown in pots of the same soil. There are differences in the genera present and in their relative numbers.

Table 3 Processes contributing to land degradation, possible remedies and consequences for the soil and environment.

Processes in land degradation	Possible remedial actions	Consequences of degradation
Protect the soil surface from erosion by wind and water.	Adopt reduced and conservation tillage. Enhance residue or living-crop cover. Establish hedges and windbreaks	Eutrophication of surface waters, flooding. Poor plant development, structural decline, reduced biodiversity.
Protect the soil from compaction and hard-setting	Build up soil organic matter, adopt machinery with appropriate axle weight limits	Landslides, poor plant establishment and restricted root development.
Protect the soil from acidification	Apply lime and animal manure, avoiding over application of N-fertilizers and manure.	Poor plant development, structural decline, reduced biodiversity.
Protect the soil from organic matter decline.	Adopt reduced and conservation tillage. Optimize crop growth to support rhizodeposition and apply organic amendments.	Greater release of greenhouse gases. Structural decline, reduced biodiversity. Loss of cation exchange capacity leading to greater loss of nutrient ions by leaching.
Protect the soil from contamination and pollution	Avoid amendments containing potentially toxic metals, use pesticides with care. Apply appropriate conservation measures to prevent wildfires.	Contamination of surface waters. Accumulation of toxic metals in plants and their entry into the human food chain.
Protect the soil from salinization or sodification	Avoid over application of fertilizers, and water and waste water for irrigation.	Greater competition for good quality water for agriculture.
Maintain the biodiversity of soil micro-, meso- and macrobiota	Adopt reduced and conservation tillage. Enhance diversity and optimize crop growth to support rhizodeposition and apply organic amendments. Apply appropriate conservation measures to prevent wildfires.	Risks from pests and invasive species.

that of any indigenous rhizobia. A sufficient concentration of microbes applied to soil and seed is necessary as rhizobia require a minimum number to act together to effect root colonization. Typically, inoculation is beneficial if the host-crop species has not been grown on the land previously so that no compatible rhizobia are present, and the supply of mineral nitrogen from the soil is inadequate for plant growth. For example, Goss et al. (2002) reported that nitrogen fixation in soybean (*Glycine max* (L.) Merrill) is reduced by 0.67 kg N ha⁻¹ for every kg ha⁻¹ of mineralized or fertilizer N present in the soil at planting. A reduction in the number of nodules is one of the factors involved, but both transcription and functioning of nitrogenase are negatively affected by the presence of ammonium (NH₄⁺). Free-draining soils are also preferred to ensure appropriate aeration. Excess water can impair oxygen supply that is essential for optimum fixation by the nodules. However, the rate of fixation in leguminous plants is also reduced when water is restricted. Co-inoculation of non-symbiotic plant growth promoting rhizobacteria with rhizobia has been used to increase nodule formation or enhance the benefits from nitrogen fixation in rhizobial symbiosis for growth. However, Zeffa et al. (2020) found no evidence for increased grain yield, following co-inoculation, from a meta-analysis of papers published over 31 years from 1987.

Inoculation of plant growth promoting rhizosphere bacteria and archaea

Concerns for impacts on the environment of nitrogen and phosphatic fertilizers together with the use of synthetic insecticides and herbicides have increased interest in the application of rhizosphere bacteria (other than rhizobia) and archaea to nursery and field crops. Bacteria that secrete antibiotics or induce systemic resistance in target plants have been applied to protect crops from disease

and pathogens. To increase nutrient availability, a broad spectrum of bacteria has been applied, such as diazotrophic (N), phosphatase-producing, phosphorus-solubilizing or hydrogen cyanide-releasing (P), ionophore or organic acid releasing (iron (Fe) and micronutrients). Inocula that contains these groups of microbes, often together with others that release plant growth promoters, including plant hormones, salicylic acid and the ethylene formation inhibitor ACC-deaminase, have been marketed as biofertilizer. For Plant Growth Promoting Rhizobacteria (PGPR) to be applied successfully in the field, they must demonstrate 'rhizosphere competence' and colonize the soil, particularly in the rhizosphere or the root (endophytes). To an extent, colonization depends on their competitiveness with other microorganisms but plants recruit specific microbial communities from the bulk soil into their rhizosphere using signal molecules, which are secondary metabolite components of their root exudates. The composition of exudates varies across plant species and with their age and the season, thereby allowing plants to influence the dynamics of their rhizobiomes. However, this is not entirely a plant-driven process. Some PGPR can change the secondary metabolites released by their rhizosphere host, thereby enhancing their coordination. Persistence of an organism within the rhizosphere will depend on its ability to maintain its metabolic functions. The soil characteristics within the rhizosphere, such as pH, nutrient availability, water supply and redox conditions, must also be appropriate. For the majority of PGPR to function fully will mean participation in biofilms that can locate in niches that allow access to sources of macro- and micro-nutrients. The requirements for colonization and persistence in the rhizosphere will influence the specifications of the inoculum delivery system and may also contribute to the challenges for successful application of biofertilizers to field crops.

The importance of the microbe selection by plants and their subsequent interactions can also have significant consequences for the efficacy of microbial inoculation for ecosystem restoration. For example, the direction of ecosystem change and the development of native plant communities from arable to grassland or dry heathland, on the same sandy glacial deposit, were greater after inoculation with unsterilized soil if the topsoil was removed rather than being left in place (Wubs et al., 2016). This highlights the significance of the population size, diversity and ability of indigenous microbes to compete for niche habitat and persist.

A final point about the use of inoculum derived from rhizosphere microbes is that there is a considerable similarity between the organisms present in rhizobiomes and those in the human gut, including some that can be pathogenic. Appropriate biosecurity protocols are necessary when soil microbiomes are used as inoculum, both to protect operatives and the wider environment. Inoculant organisms may alter the balance of the existing consortium of microbes in the rhizosphere, possibly modifying the microbiome functioning, and if persistent could pose the risk of later invasive spread in the presence of other crops. Significantly, the use of fungal inoculants has changed bacterial populations in a majority of examples assessed, generally leading to greater diversity, whereas bacterial inoculants increased diversity in only 66% of examples (Cornell et al., 2021).

Inoculation with mycorrhizal fungi

Although mycorrhizal fungi are commonly associated with many species of host plants, similar to the situation with rhizobacteria, there is also strong evidence of host-driven selectivity for the AMF present in the roots of individual plants and species. The signal exchange dialogue between plant and fungus, which takes place before root colonization starts, is an important component of the selectivity. Land use and management intensity affect the abundance and species richness of AMF from which host selection can take place. Very degraded soils probably have an inadequate supply or quality of AMF propagules and hence can benefit from inoculation. Other soils, such as those supporting temperate grassland, may have an overwhelming abundance of propagules that originate from an AMF community of considerable richness and can out-compete any introduced inoculum.

Colonization results from three types of propagules: spores, extraradical mycelium (ERM), and colonized root fragments. Spores are the easiest propagules to produce as commercial inoculum, but there are issues related to germination and viability after production and limitations to the diversity of species that are readily amenable to the processes involved. Colonized root fragments, together with spores, are likely to be present when freshly collected soil samples are used as inoculum. Although ERM can remain viable in soil after freezing or drought, it rapidly loses infectivity following disturbance (Addy et al., 1997; Goss et al., 2017). Thus, for ERM to be important as a propagule, it needs to have developed from colonized roots, and for roots of target plants to explore the same undisturbed soil volume as that explored by the mycelium. This has resulted in experimental systems that grow 'nurse' plants, colonized by one or more selected AMF to produce ERM that infects batches of serially germinated target plants. The members of each batch all become colonized at the same time and more rapidly than typically achieved using spores. This concept can be exploited in agriculture and horticulture (see Section "Examples of managing AMF") but does not lend itself to being the basis for a commercial inoculum.

The establishment of a mutualistic symbiosis between a mycorrhizal fungus and the roots of its plant host takes place in the presence of all other microorganisms in the immediate rhizobiome. There is evidence from using fresh soil as an inoculum in the field and direct laboratory studies, that some soil microbes, especially bacteria, contribute to the success of the process and promote mycorrhizal development. Both AMF and ectomycorrhizal fungi (EMF) are associated with rhizobacterial strains, 'mycorrhiza helper bacteria' (MHB), that support the development and establishment of their symbioses. There are also bacterial endophytes found within the hyphae of AMF that also support the formation of the mycorrhiza. The specificity of MHB for the fungal partner is still uncertain. Within the MHB, there are strains that stimulate the germination of mycorrhizal fungus spores, modify the radial growth of fungal mycelium or increase the branching of hyphae, all important for the initial colonization process. At the same time, some MHB can influence the architecture of the host root system leading to enhanced branching and to longer branch roots. The combination of these effects on fungus and host roots could contribute to increased root colonization. However, the formation of more root tips and hyphal branches could be equally beneficial in enhancing the signaling between potential symbionts. Greater exchange of signals together with release of plant hormones or any deficient nutrients could also result in greater colonization. The

identification of appropriate MHB of specific mycorrhizal fungi can increase the efficacy of mycorrhiza formation, requiring less propagule material. Other bacteria associated externally on fungal hyphae appear to operate symbiotically, with the physiology of both partners showing changes.

Mycorrhizal fungi and soil bacteria typically form biofilms in soil, and fungal hyphae can act as the substrate for their formation by bacteria or be part of a consortium of microbes in a common biofilm. There is significant interest in the inoculation of organisms, which on being applied to soil readily form a common biofilm and can recruit additional members. Such a technique or the application of organisms, already part of a biofilm, to soil could help overcome the problems of ensuring the persistence of beneficial microbes after inoculation and keeping synergistic partners together for long enough to influence target plants.

Reliability of inoculation

What is clear from assessments of empirical studies is that the success of inoculation to manipulate the soil biota depends on effecting positive changes to the biodiversity of the indigenous community. Changes to the biodiversity of bacterial communities can be achieved through both fungal and bacterial inoculants. Although positive changes are reported, negative change and no-change are frequently reported, indicating a lack of reliability in implementing this management practice.

Exploitation of indigenous microbes

In a critical review of the performance of P-solubilizing bacteria in the field, [Raymond et al. \(2021\)](#) argued that they do not mobilize enough P to alter the nutrition of a crop under field conditions. These authors recommend that a more promising approach would be to support the indigenous soil microbiome in the mobilization and cycling of P. Numerous studies have reported that the application of local inoculum from a similar soil, which contains vital whole microbial communities, is more effective in improving plant performance than the addition of individual exotic species or strains. In agricultural ecosystems, the opportunity for in-situ exploitation of indigenous microbes is even greater than for restoration of natural ecosystems.

Pre-requisites for ensuring appropriate levels of biological and functional diversity in soil microbiomes

Establishment of a resilient soil biology depends on maintaining suitable habitats for the organisms that comprise the soil food web. Restricting disturbance of soil mechanically, chemically or biologically helps stabilize soil structure, maintain niche habitats, biofilms and mycorrhizal ERM networks, prevents the accumulation of excess mineral nutrients, toxic metals and organic molecules, and encourages cooperative activity or syntrophy. Effectiveness of the food web depends on ensuring a supply of easily accessible organic matter that can support the numbers and diversity of soil microbes. In turn, this supply of energy drives the soil carbon and nitrogen cycles and releases other macro- and micro-mineral nutrients. Rhizodeposition, root turnover and plant residues all contribute to the provision of organic matter but additional external sources, such as compost or animal manure, might be required. The actions of roots, soil fauna and microbes link soil particles to organic matter and form microaggregates, which combine into macroaggregates and then into structured soil. The pores within and between aggregates provide trophic niches and store or transport water and air. Soil organisms and roots further mold the soil to create larger pores for their own passage. The organic molecules released by roots of different plant genotypes attract consortia of microbes into the rhizosphere from the bulk soil that differ in the taxa present and relative numbers of individuals present. Precise membership of the consortia changes with the age or growth stage of the plants and is further influenced by soil and environmental factors.

Many of the actions associated with agronomic activity can impact, positively or negatively, on this complex balance within the soil. In the context of microbe management, agronomic practices need to be selected by taking into account their potential influence on soil microbial diversity and activity.

Farming systems and agronomic management practices

Three major farming systems dominate crop production: conventional systems that rely on mineral fertilizers to provide the main nutrients for the crops and annually till the soil to prepare a seedbed; organic systems that use animal manure, vegetable compost and cover crops to supply most of the nutrients but the soil is nearly always tilled annually; conservation systems that aim to protect the soil from erosion and conserve its ability to provide key ecosystem services, particularly by reducing excessive cultivation in favor of limited or strategic tillage practices. In addition to nutrient management and tillage practices, weed and disease control tend to differ between farming systems, with conventional and conservation systems relying on chemical control. Individual producers may adopt a package of measures selected from some or all the major systems.

Practices associated with each of the main management areas – tillage, cropping system, nutrient and disease management – may have positive or negative effects on soil biota, therefore, they provide opportunities to manage the direction and extent of any resulting change.

Tillage

The main tillage systems and their consequences for soil properties and microorganisms are summarized in [Table 4](#).

Table 4 Characteristics, aims and some essential effects of various tillage systems and their potential impacts on soil microbes.

<i>Tillage technique</i>	<i>Main machines involved</i>	<i>Principal aims and effects achieved</i>	<i>Possible effects on microorganisms</i>
Inversion tillage	Mouldboard plough, offset disks	Effects inversion of the soil. Disturbs and fragments the soil; buries weeds and residues from the previous crop, incorporates manure and both organic and inorganic amendments. Conventional tillage is usually associated with the use of the mouldboard plough. Increased risk of soil erosion.	At the plough layer, roots, AMF mycelium and biological channels are disrupted. Soil organic matter (SOM), less mobile nutrients and spores are distributed more uniformly. Biofilms are likely to be disrupted. AMF community is changed in favor of species that produce more spores.
Ridge till	Ridge tillage cultivator and modified planter	Soil is pushed by pairs of winged tines to form ridges up to 20 cm deep. The harvest residues on the surface are removed and the top of the ridge flattened by a horizontal blade so that the seed is planted in the ridges without residue cover in the row. Contrasting soil conditions are created in the ridge and between the ridges. Residues and organic amendments are mixed with soil in the sides of the ridges each year. The ridges warm up quicker than flat land in spring, in part because the ridges drain more readily.	At the inter-rows, there is little root development. In the ridges, SOM builds up and conditions for root development and microbial growth are improved. Once ridges are formed, there is little disruption of microbes. Biofilms near the center of ridges are largely protected as are AMF that preferentially start new infections from intact ERM.
Reduced tillage	Rigid or sprung tines	No soil inversion. Typically harvest residues are left on the soil surface.	The disruption of roots, AMF mycelium and biopores is partial. Stratification of SOM, less mobile nutrients and spores is favored.
Deep reduced tillage	Rigid tines	Non-inversion tillage to a depth greater than 100 to 150 mm.	The disruption of roots, AMF mycelium and vertical biopores is partial.
Shallow (reduced) tillage	Rigid or sprung tines	Non-inversion tillage to a depth of less than 100 mm.	The disruption of roots, AMF mycelium and biopores occurs in the disturbed soil. Residues remain covering the soil surface
Stubble-mulch tillage	Tines or disks	Residues retained on the soil surface, with soil disturbance without inversion	Disruption extensive to the depth of the tillage tool.
Zero-tillage/no-till/direct drilling	Drill with combination of tines or disks	Seed is drilled into the stubble of the previous crop with minor soil disturbance confined to the row and does not extend below seeding depth. Soil conditions are closer to the ones found in the natural environment if compaction can be avoided. At the micro-scale there is the opportunity for contrasting ecological niches to develop in the soil.	Roots, AMF mycelium and root channels are left undisturbed. Stratification of SOM, less mobile nutrients and spores is maximized. Biofilms are not disrupted, except in the seed row. AMF species that produce less spores are protected.
Zone or Strip-tillage	Rigid or sprung tines	Zone-tillage is a development of no-tillage crop production. It consists of tillage with coulters or rigid tines (down to 15 cm below the soil surface) in a narrow strip of soil. Seeding takes place in the tilled zones, with the inter-row area remaining undisturbed and retaining crop residues.	The disruption of roots, AMF mycelium and roots channels are partial. Stratification of SOM, less mobile nutrients and spores is favored. In a large scale, contrasting soil conditions are induced between tilled and no-tilled zones. In the latter, soil conditions will be similar to no-till systems.
Strategic tillage	Rigid or sprung tines, mouldboard plough	A system predominantly using reduced tillage equipment but includes the use of mouldboard ploughing as a flexible responsive to seedbed concerns (typically weeds) or the need to incorporate organic amendments, manure or crop residues. Avoids long-term development of soil conditions typical of natural soils.	Roots and AMF mycelium periodically disrupted
Rotational ploughing	Rigid or sprung tines, mouldboard plough	Reduced tillage or no-till is used routinely for soil preparation but a plough is used at key points in the rotation	Roots and AMF mycelium periodically disrupted
Secondary tillage	Powered or unpowered tines, disks, rotary implements, rollers	Tillage practices used after the principal tool to create a seedbed and provide additional weed control	Completes disruption of roots, AMF mycelium and biopores throughout the depth of operation. Homogenises the distribution of soil organic matter, immobile nutrients and spores.
Remedial tillage	Subsoiler tines, rotary spades or mole plough	Tillage used when required to remove compacted layers or improve water movement	Improves air-filled porosity and the continuity of vertical structural pores and increases the depth of rooting

The effect of conventional tillage on soil biology is both physical and chemical, with the direct impact of implements, disruption of structure and abrupt changes in aeration and water content. The latter is mainly the result of moist soil from depth being brought to the surface. Action of ploughs and tines disrupts fungal hyphal networks and breaks up root systems and stems infected by soil-borne pathogens, reducing the size of individual sources and consequently their inoculum potential. The uniformity of soil organic carbon (SOC) content and pH in the profile and the imposed changes in soil structure, together with the direct impact on earthworm populations and burrows, also reduce the diversity of trophic microsites within the tilled layer and the populations of microorganism within them. The effects of reducing tillage depth and adoption of conservation measures are similar but confined to shallower depths. The lack of inversion likely reduces the scale of any change in aeration and water, except in zones of previously compacted soil. Under no-till, drying of the soil surface may be reduced because of the presence of crop and harvest residues, which also aid infiltration and protect from erosion and raindrop impact. The reduced physical disruption and absence of inversion improves the stability of soil aggregates, which protects against erosion and consolidation, and helps to maintain porosity and pore continuity. The inherent heterogeneity in structure can lead to differences in microbial biomass and microbial diversity. Similarly, the contrast in distribution of SOC and variability in food resources between tillage systems can influence the location and diversity of soil organisms within the profile. In terms of inducing the effects of both structural and chemical heterogeneity, chisel ploughs can be as effective as no-till (Zuber and Villamil, 2016).

Within the soil macrofauna, gastropods, arthropods, earthworms and insects have been considered sensitive to soil disturbance, although experimental results are more variable.

Archaea and bacteria show responses to tillage but the scale of study is important. At the scale of soil aggregates, no effects on abundance are found but where tillage reduces aggregation or number of aggregates, then abundance is less. Effects of conventional tillage tend to reduce the abundance or biomass of microbes near the soil surface, but when considered over the depth of the soil profile differences between ridge-till and no-till are not significant. In shallow-tilled soil, impacts in the disturbed layer are similar to those of conventionally tilled soil. Certain groups of archaea, bacteria and fungi are more associated with conventional cultivation, whereas other groups are mostly found in untilled soil (Table 5). For example, anaerobic methanogenic archaea are more commonly reported in no-till. However, a reduction in soil disruption is associated with increased diversity of organisms (especially minor representatives) and their level of activity (Table 6). The added input of crop residues under conservation tillage can also support a larger abundance of microbes (Table 6).

Given the changes that can result from full inversion tillage, it can be used as a means of resetting the microbial population to a point that a new crop can establish its own rhizobiomes, free from well-established sources of root disease organisms and other imbalances. It is a common practice to use tillage to overcome replant issues for ginseng (*Panax ginseng* C. A. Meyer).

Nutrient management

At maturity, plants have accumulated different contents of nutrients according to their needs for growth and development (Table 7, Tubeileh and Goss, 2022). Even for the macronutrients N, P and potassium (K) the variation is considerable between plants in the same family (e.g., maize – *Zea mays* L. – and rice – *Oryza sativa* L. or chickpea – *Cicer arietinum* L. – and alfalfa – *Medicago sativa* L.). To meet plant requirements for nutrients in agricultural and forestry ecosystems, mineral fertilizers and organic amendments, such as animal manure, are applied to maintain the amounts available in soil. In addition to mineral forms of N and P, manure also contains organic forms, micronutrients and other carbon compounds. The latter contribute to the soil stock of SOC that can greatly enhance the number of bacteria in soil, but the effect on fungal populations is small in the absence of organic-based nutrient additions (Fig. 2).

The contributions of soil organisms to the availability of macro- and micro-nutrients in soil (described above) are also influenced by the form of nutrients used in replenishing them. Application of mineral fertilizers, particularly ammoniacal-N fertilizer, can result in acidification of soil, whereas animal manure tends to increase soil pH. Variation in soil pH greatly influences bacterial abundance, with decreases in total microbial biomass below pH 5 but increases above and in community composition (Fig. 3). Mineral N fertilizer alone, particularly at annual applications of 100 kg N ha⁻¹ (e.g., Zhou et al., 2017), tends to decrease microbial biomass, whereas smaller applications and meeting crop needs for P and K as well as N may result in increased microbial biomass. The effects on Gram positive (GM⁺) bacteria are different from those of Gram negative (GM⁻), resulting in an increase in the ratio of GM⁺:GM⁻. Effects on bacterial diversity tend to reflect the differences in biomass. However, diversity may not be reduced if N is applied together with either P or K rather than combined with P and K. The exception to this pattern of response to N-fertilizer is in anaerobic soils, such as those growing paddy rice, where the application of N alone increases bacterial diversity.

Nutrient management practices, including the application of lime to decrease acidity, greatly influence the composition of soil bacterial communities. For example, Chinnadurai et al. (2014) reported that the greatest number of phyla was associated with soil receiving mineral fertilizers, which also contained one phylum not found in other treatments (Fig. 4B). Furthermore, the relative abundance of bacteria in the major phyla varied between soil receiving mineral and organic forms of nutrients, and both differed from that in the control where no nutrients were applied (Fig. 4A and C).

The abundance of the amoA genes from ammonia oxidizing archaea (AOA) and ammonia oxidizing bacteria (AOB) reflects the numbers of organisms present. Application of N produces greater increases in amoA gene abundance in AOB than in AOA. The response is unrelated to the rate of N application but to the total load of N applied. However, AOB are more responsive to mineral-N than to organic-N but AOA respond similarly to both forms. The smaller AOB populations in soils with no history of receiving additions of N show a Greater reaction than those under agricultural or grazed grassland management. In contrast, AOA show a greater response to N in agricultural arable soils than in pasture soils.

Table 5 Examples of Archaea, Bacteria and Arbuscular Mycorrhizal Fungi that are more commonly associated with particular tillage regimes at various taxonomic levels.

<i>Domain</i>	<i>Phylum</i>	<i>Order</i>	<i>Family</i>	<i>Genus (Species)</i>
a) Conventional tillage: disturbed habitat				
Archaea	Nanoarchaeota	Woesearchaeales		
Archaea	Thermoproteota

Table 6 The effects of different tillage systems on key parameters of microbial functioning.

<i>Microbial parameter</i>	<i>Tillage System</i>			
	<i>Conventional tillage</i>	<i>Ridge-till</i>	<i>No-till</i>	<i>Conservation tillage</i>
Microbial biomass/abundance	++	+++ ^a	+++ ^a	+++
Microbial diversity	++	+++	+++	+++
Biological activity	++	+++	+++	+++

^aIndicates that increases occur in some layers but summed over the soil profile, effects are not statistically significant from conventional tillage.

Table 7 Approximate content of macronutrients in some agricultural crops at harvest and in typical animal manures from farms, expressed in g kg⁻¹ dry matter, together with their ratio, based on P.

	Nutrient content (g kg ⁻¹)			Nutrient ratio
	N	P	K	N:P:K
Crop				
Maize (<i>Zea mays</i> L.)	13.5	1.8	14.1	7.5:1: 7.8
Rice (<i>Oryza sativa</i> L.)	9.3	1.6	10.3	5.5:1: 6.4
Wheat (<i>Triticum aestivum</i> L.)	12.4	1.3	13.8	9.5:1:10.6
Oat (<i>Avena sativa</i> L.)	9.0	1.8	16.9	5.0:1: 9.4
Soybean (<i>Glycine max</i> L. Merr.)	31.7	3.8	15.4	8.4:1: 4.1
Chickpea (<i>Cicer arietinum</i> L.)	19.9	4.0	10.7	5.0:1: 2.7
Lentil (<i>Lens culinaris</i> Medik.)	15.9	2.9	13.7	5.5:1: 4.7
Alfalfa (<i>Medicago sativa</i> L.)	39.9	3.3	29.3	12.1:1: 8.9
Manure				
Liquid manure, dairy cattle	3.5	0.8	2.4	4.3:1: 3.0
Solid manure, beef cattle	7.4	2.4	5.7	3.1:1: 2.4
Liquid manure, pig	4.0	1.3	1.8	3.1:1: 1.4
Solid manure, chicken (layer)	19.3	8.9	8.0	2.2:1: 0.9

Modified from Tubeileh AM and Goss MJ (2022) Assessing the effects of using animal manure on soil health. In Horwath R (ed.) *Improving Soil Health*. pp. 281–308. Cambridge, UK: Burleigh Dodds Science Publishing.

**Fig. 2** Effects of changes in soil organic carbon on the populations of bacteria and fungi in a sandy loam (Typic Haplustalf). The largest populations of both bacteria and fungi were present in soil receiving organic amendments (composted cattle manure). Data from Chinnadurai et al. (2014).

The form of nitrogen application, organic amendment or mineral fertilizer, also changes community composition of both bacteria and fungi (Toljander et al., 2008). The application of ammonium sulphate, (NH₄)₂SO₄, fertilizer or sewage sludge affects community structure very differently. Some changes result from arrival in the soil of dominant phyla present in the sewage sludge, whereas others stem from stimulation of the indigenous population by some of its components. Organic amendments can favor Ascomycota fungi, although saprotrophic fungi may not be affected by nutrient addition, whether as NPK mineral fertilizer or as cattle manure. However, application of mineral nutrients can result in reductions of AMF colonization and growth of ERM. In contrast, increases of both these variables, together with the number of AMF species present, can result if soil only receives nutrients with the application of manure. Toljander et al. (2008) found that the number of AMF species and composition of the community were influenced by the form of N applied. These changes can also be associated with modifications to soil pH resulting from the mineral fertilizers (increased acidity, lower pH) and manure (decreased acidity and increased as pH) as an important factor modifying the microbial community structure, particularly of bacteria.

Changing the availability of N in the soil, such as by making N applications that are greater than 100 kg N ha⁻¹, can be associated with a decline in root colonization by AMF and a reduction in their abundance. However, as such effects are not uniform across all AMF taxa, the relative abundance of taxa and hence the AMF community composition can be modified. In turn, that can influence the community composition of host plants. Nevertheless, addition of mineral N may have no significant effects on species richness

Fig. 3 Relative abundance of some major bacterial phyla in communities across 88 soils from North and South America grouped according to pH. Data from Lauber et al. (2009).

or diversity of AMF, a response that is strongly linked to the relative availability of soil P (i.e., the soil available N:P ratio). Application of N to soil with an adequate content of available P appears to increase the likelihood of a negative effect on AMF. In contrast, increased N supply, when P availability to host plants is limiting in the absence of mycorrhiza, may stimulate plants to provide more carbon and thereby enhance AMF presence, consequently obtaining more P.

The carbon cost to the plant per unit of N gained can be three times less when it is mycorrhizal than when it is not. Furthermore, AMF are more efficient in obtaining N from organic sources than from mineral fertilizer (Chowdhury et al., 2022). Although AMF hyphae lack the key enzymes required to mineralize N from organic matter, they can take up many amino acids. The AMF take up both NH_4^+ (via transporters) and NO_3^- (following conversion to NH_4^+ by nitrate (NO_3^-) and nitrite (NO_2^-) reductases) and convert the mineral-N into amino acids. Importantly, NH_4^+ is the form of N transported across the arbuscule-plant membrane interface and into the plant. The release of exudate from ERM hyphae helps recruit a selection of soil bacteria to the hyphosphere (the equivalent of the rhizosphere for ERM), including the hyphal surfaces, which allows the ERM from mycorrhizal plants to exert control over mineralization of organic N through the functioning bacterial population that accompanies it.

No unique relationships have been identified between individual decomposers, which mineralize N but only make it available to the ERM of specific AMF. This generalized interaction between AMF and microbial decomposers in the provision of N contrasts with the release and uptake of P from phytate. The AMF have been shown to provide a route, via the surface of extraradical hyphae, by which particular mobile microbes can reach and release mineral-P from the organic source in soil, as exemplified by *Rahnella aquatilis*, a member of the Gammaproteobacteria, and the AMF, *Rhizophagus irregularis* (Jiang et al., 2021).

A key aspect of the response of AMF to P is the effect on the symbiosis and how the interdependency might change, especially in agroecosystems. The AMF colonization usually declines with increasing concentrations of available P (Covacevich et al., 2007). However, depending on the soil and crop, there is a critical value of P (between 25 and 30 mg P kg⁻¹) beyond which the level of colonization stabilizes (Fig. 5). The number of AMF species and community structure present in the soil and the density of ERM hyphae (m g⁻¹ soil) decline with soil available P (Lang et al., 2022). Furthermore, the reduction in species abundance can limit the range of mutualism that is available to host plants to meet their requirements for nutrients. The question then arises, "How important to AM symbiosis is the provision of a greater supply of P to the host plant?"

Plant roots typically take up P as dihydrogen phosphate (H_2PO_4^- , P_i) from soil via high-affinity transporters in their epidermal, root hair, and outer cortical cells – the direct uptake pathway (DUP). But when colonized by AMF, a second, symbiotic (SUP) pathway is provided by the fungal symbionts. At larger concentrations of soil P, growth and P_i uptake by mycorrhizal plants may not differ greatly from non-mycorrhizal controls, suggesting that there is no benefit from the mycorrhiza formation. However, AMF vary in the ways they influence the SUP and DUP pathways. It is clear that in mycorrhizal plants, the DUP can be modulated independently of the P_i status through the interaction with SUP (Fig. 6). Importantly, ERM networks can also mediate a reduced supply of P_i by DUP locally, but without affecting that in distant roots, which may not yet be colonized. It also means that solely basing assessment of the benefits of mycorrhiza formation on enhanced P_i provision is inadequate (Facelli et al., 2014).

Fig. 4 Effects of nutrient management practices on bacterial community structure. (A) Number of major (plain bars) and minor phyla (hatched bars) present under different nutrient management regimes (B) Variation in the total number of phyla present in soil (plain bars) and the number of phyla also present in soils under the other nutrient practices (hatched bars). (C) The relative abundance of bacteria in the major phyla varies between soils with the distribution showing more evenness where organic forms of nutrients were applied. The largest populations of both bacteria and fungi were in soil receiving organic amendments (composted cattle manure). In the 'Mineral fertilizers' treatment, nutrients in the form of urea (N), super phosphate (P) and muriate of potash (K) was applied in the elemental ratio of 7:1:1. No nutrients were supplied to the 'No amendments' treatment. Data from Chinnadurai et al. (2014).

Fig. 5 Effect of phosphate availability on AMF colonization in wheat and maize at vegetative and reproductive stages of growth. Closed and open markers indicate results for 2010 and 2011, respectively. Arrows indicate the break from a general decline in colonization with P concentration to a plateau level of colonization, which is greater for maize than wheat. Critical values of available P range between 10 and 31 mg P kg⁻¹ (Data from [Deng et al., 2017](#)).

The impact of P on AMF colonization suggests that consideration of the distribution of fertilizer P in the soil is important. Under no-till systems, a strong stratification in P concentration results in greater concentrations of P closer to the soil surface than with inversion tillage. Broadcasting of fertilizer enhances this effect. Such information supports the view that fertilizer banding can offer a strategy to reduce the proportion of roots that are exposed to negative impacts of large amounts of soluble phosphate. In similar vein, for small grain cereal crops grown under no-till, broadcasting P fertilizer might reduce maximum soil P concentrations compared with deep banding, and have less negative effect on AMF colonization. Under intensive agricultural systems, deeper soil layers with smaller P concentrations could encourage colonization by a more diverse AMF community than in enriched superficial soil layers.

The abundance and diversity of AMF appear to be enhanced under organic agriculture relative to conventional farming, probably owing to the positive impact of using organic forms of P. However, the differences in abundance and diversity are related to a loss of taxa under intensive conventional agriculture rather than changes in species. [Såle et al. \(2015\)](#) found a greater number of AMF species under organic farming only when reduced tillage was used, but under inversion tillage there were no differences in the number of AMF species between organic and conventional systems. However, benefits from organic forms of P also depend on the type and amount of organic amendment. Consequently, as there are generally several differences in cropping systems between farming types, the impact of the latter is not always easy to interpret.

The cropping system is also a factor in the AMF response to P. For example, abundance of AMF species present in soil was significantly greater under a 7-year crop rotation than under a maize monoculture receiving the same application of mineral P fertilizer ([Oehl et al., 2003](#)), and benefits of rotation occurred even where large amounts of nutrients were applied.

The contribution of AMF to plant P uptake and growth seems to be greater when the nutrients are released from organic sources rather than provided by mineral fertilizers, even where plant P content is the same. Therefore, the large-scale adoption of strategies

Fig. 6 Effect of soil phosphate (P_i) supply on colonization and uptake of P of two genotypes of the annual medic *Medicago truncatula* (wildtype A17 and the mutant, *dmi1*, that is unable to establish symbioses with rhizobia or AMF) in association with 2 AMF (*Rhizophagus irregularis* or *Gigaspora margarita*). (A) Increased P_i supply reduced the percent root length colonized by either fungal symbiont. Colonization of mutant *dmi1* by AMF was zero or negligible when the plants were grown in single culture (1-genotype) but was somewhat greater when grown in mixed culture with wildtype plants, although very few arbuscules were present. (B) Shoot P content of wildtype A17 derived from the direct uptake pathway (DUP) through roots and that derived from uptake via extraradical hyphae of the AMF (SUP). With *R. irregularis* the SUP pathway consistently provided less P to the shoots from low P_i (plain bars) than high P_i available soils (hatched bars) but the separate supplies via the two pathways were similar, although when the plants were grown in mixed culture with mutant *dmi1*, SUP was greater than DUP. With *G. margarita*, the SUP pathway supplied less P from soil of high P_i compared with low P_i , whereas the supply via DUP was greater from the soil of high P_i . Furthermore, the supply from DUP was always greater than that from SUP. When the two genotypes of *M. truncatula* were grown together, the DUP was similar to the SUP attained with *R. irregularis*. (C) Shoot P content of both genotypes derived from the direct uptake pathway (DUP) through roots. Even in the absence of AMF, DUP for P by the wildtype, A17, was greater when grown in mixed culture with mutant *dmi1* in high P_i soil. Uptake by mutant *dmi1* was similar to that of the wildtype in the absence of AMF in both high and low P_i soils, but in their presence, uptake was reduced when the plants were grown in mixed culture with wildtype and when grown in single culture if the AMF was *G. margarita*. Data from Facelli et al. (2014).

to improve SOM, such as conversion to reduced or no-till systems, maintenance of crop residues on the soil surface, the inclusion of cover crops and use of organic fertilizers, would certainly make a major contribution to improvement in the sustainability of agricultural systems. Such strategies would also enhance the potential role that AMF can play, either in agricultural systems where excessive levels of fertilizer application are a concern for water quality and AMF biodiversity, or in those regions of the world where inputs of nutrients are only moderate, or even too small, and consequently cause concern for soil productivity.

Cropping system

Crop rotation is consistent with the aims of sustainable agriculture in maintaining soil fertility and increasing productivity, restricting buildup of pathogens and weeds, improving crop nutrition and soil structure through fuller exploration by contrasting root systems.

A typical crop rotation involves a repeated sequence of monocot and dicot crops grown in a pure stand, although mixed stands and strip cropping may be used. Ideally, the mixture of plants includes some that are shallower and others that are deeper rooting. Rotations may include crops that are not grown to maturity, such as forage, cover or catch crops. Some systems include a perennial crop with annual crops sown between the individual perennial plants. Variation in the components of the residues from different crops is a significant factor in determining soil properties, with leguminous plants providing a source of nitrogen that can help alleviate yield loss associated with plough-down of grassy pastures. However, some crops, such as brassicas, may be particularly beneficial in inhibiting pathogens but may also have adverse effects on beneficial microbes: being non-mycotrophic they inhibit both the diversity and numbers of individual AMF species, in part because of their inhibitory effects on spore germination.

Soybean and maize in a crop rotation improve the nutrient content of soil primarily by influencing composition of the bacterial community, especially the Gram-positive bacteria. [Dorr de Quadros et al. \(2012\)](#) compared rotations that were a combination of cereals (oat- *Avena strigosa* Schreb, grown in winter and spring-sown maize.) or a simple combination of a legume (*Vicia sativa* L.) grown in winter with spring-sown maize, or a combination of cereal and legume grown in each season (oat and *V. sativa* grown in winter and maize and cowpea (*Vigna unguiculata* L.) in summer. Based on the analysis of 16S rRNA gene sequences, cropping systems had a large effect on microbial community structure. The oat-maize rotation had the greatest diversity of bacteria, based on the Shannon index. However, the rotations that included legumes resulted in soils that were significantly more acidic, which would tend to reduce abundance and diversity ([Fig. 3.](#)).

Improving the potential contribution of AMF to agricultural systems requires crop rotations (including cover crops) to be designed that take account of the key role of plant hosts to maintain species richness and diversity. Legumes are associated with greater diversity than grasses or herbs, with C_4 grasses being more responsive to AMF than C_3 . Alternating cereals and legumes in cropping systems seems to improve the benefits of AMF, which might be because grasses and broadleaved herbaceous plants act as distinct groups of functional host plant, or offset negative feedback mechanisms if grown in monoculture. Such results highlight the potential of particular cropping systems to have contrasting effects on different groups of microorganisms.

Cover crops, particularly combined with no-till, should also be considered as a key element in the management of microorganisms, and can be an important means to improve the diversity of soil microbes in perennial systems, such as orchards. A diversified crop rotation, provided the component species are mycotrophic, can be especially important for the abundance and diversity of AMF. Cover crops of mixed species can be advantageous for these same reasons. Restoration of AMF inoculum potential in soil following non-mycotrophic canola (*Brassica napus* L.), fallows, or lengthy periods made unfavorable for plant growth by drought or cool temperatures, can be achieved using cover crops ([Kabir and Koide, 2002](#)). Importantly, intact hyphae can survive and remain infective after a dry hot summer (Mediterranean climate) or a cold temperate winter. Such use of cover crops might have less scope under rainfed agriculture, where there is insufficient water to grow two crops in a year. Any mycotrophic weeds that germinate at the beginning of the planting season can increase colonization of the crop, its growth and P uptake if they are controlled by herbicides and the crop is seeded without soil disturbance (see [Goss et al., 2017](#)).

Chemical crop protection

The main crop protection chemicals aim to control weeds and pests, the latter focused on fungi, insects and nematodes. Management of weeds, fungal diseases together with the impact of nematodes and insects also involves the risks associated with increased resistance of target species because the chemicals employed lack diversity, including their modes of action. Furthermore, although reduction in target groups, such as fungi or nematodes, would be anticipated, direct adverse effects on other organisms could be of concern if environmental services are threatened. Indirect effects may occur if the removal of target organisms changes the availability of resources to competitors. The direct effects on non-target soil organisms of the range of pesticides, commonly applied in world agriculture, was tabulated by [Bünemann et al. \(2006\)](#) who concluded that these increased from herbicides to insecticides and fungicides. There was considerable variation between chemicals in responses to single or repeated applications, and in the affected non-target species. The herbicide, glyphosate, which is widely used world-wide, modified microbial community structure leading to increases in fungi but reduced the presence of phosphatase enzymes in soil. For bacteria, [Newman et al. \(2016\)](#) found that members of the phyla Proteobacteria, Acidobacteriota, and Actinobacteriota dominated maize and soybean rhizospheres, but application of glyphosate increased the relative abundance of Proteobacteria (particularly in the class, Gammaproteobacteria) but decreased that for Acidobacteriota. The effect of herbicides on AMF colonization is also inconsistent, for example glyphosate has been reported to have no effect (see [Goss et al., 2017](#)). Negative effects of the herbicides bromoxynil and paraquat on AMF colonization have been reported when they were incorporated directly into the soil ([Abd-Alla et al., 2000](#)), but diclofop-methyl, diflufenican and bromoxynil applied to soil had no effects, neither did spraying weeds with paraquat. Regardless

of the impact, soil tillage is the alternative to the use of herbicides for weed control, which can have negative effects on the diversity and abundance of soil microbes, especially AMF.

Neonicotinoids have been the most widely used insecticides in the last decade. However, their impact on non-target insects has been severe, partly because of their persistence within crop plants, which can last for up to 200 days in wheat. Commonly applied as a seed coating, 80% may remain in the soil for up to 3 years with 20% taken into the plant. In a 3-year soybean–maize–soybean rotation on a clay-loam soil, 294 bacterial zOTU were significantly different in abundance between neonicotinoid-treated samples and controls; 68 were more abundant, whereas 226 (>60 genera) had reduced abundance (Parizadeh et al., 2021).

Fungicides are potentially the most deleterious pesticide for AMF. However, when applied at field rates, effects on mycorrhizal development depend on the active compound. Systemic fungicides do not appear to have greater effect on the formation of mycorrhiza than contact types. Fungicides are probably more detrimental to AMF development when applied as a seed coating than if plants, already mycorrhizal, are treated. However, development also seems to depend on the active compound and some have no-effect or even stimulate AMF (Plenchette et al., 2005). When methyl bromide was an acceptable soil fumigant, it was evident that species richness and diversity of AMF could recover from a single fumigation (67% methyl bromide, 33% chloropicrin) by the end of the growing season, even though repeated use could result in the complete absence of root colonization.

Disease suppressive soils

A particular issue for achieving appropriate levels of biological and functional diversity in soil occurs in disease suppressive soils, where genera of particular Phyla can dominate the rhizosphere of crops and suppress root pathogens. One, well-researched system is ‘Take-all suppression’ in soils on which a cereal rotation of wheat and barley (*Hordeum vulgare* L.) or oat (*Avena sativa* L.) is grown continuously for several years. Take-all in wheat is caused by the fungus *Gaeumannomyces tritici*, which also infects barley and some other grasses but not oat. The fungus enters the root system and invades the phloem and xylem of the plant.

Detailed analysis of Take-all shows that within the rhizosphere of wheat are numerous genotypes belonging to the *Pseudomonas fluorescens* complex, which produce the antibiotic phenazine-1-carboxylic acid (PCA) that helps to prevent root invasion by fungi, including *G. tritici* (Kwak and Weller, 2013). The level of root colonization and PCA accumulated after production by these bacteria is inversely related to the amount of rainfall or irrigation water received, whereas the severity of Take-all is less under dry conditions. Biofilm formation is more robust and antibiotic formation is enhanced by the PCA-producing microbes in drier soil. Another antibiotic, also produced by pseudomonads and some other bacteria in the rhizosphere, is 2,4-diacetylphloroglucinol (DAPG), which inhibits viruses, bacteria, fungi, and oomycetes. In addition to its direct action against microbes, DAPG primes the induced systemic resistance mechanism of plants, which is an enhanced defensive capability that acts against a broad spectrum of pathogens. The DAPG-producers are particularly significant in the suppression of soilborne pathogens in monoculture, for example, pea (*Pisum sativum* L.) and small-grained cereals. Under cereal monoculture, DAPG-producers accumulate within the rhizosphere until they reach 10^5 CFU g⁻¹ root, sufficient to suppress the invasive actions of *G. tritici* and ‘Take-all decline’ begins. The complex actions of DAPG appear to be sufficient to prevent *G. tritici* from developing resistance to the antibiotic (Kwak and Weller, 2013). It is clear that in these soils, during monocropping, the microbiome is not as biologically diverse as in mature natural ecosystems.

Approaches to manage soil microbes in farming systems

There is evidence that key aspects of agricultural field management affect the soil microbial population non-randomly and modify the potential for plant growth. The addition of different plants has a marked effect on the rhizosphere population because of the selection and recruitment by the introduced plant roots. A rational use of organic and inorganic nutrients needed to maintain soil reserves is compatible with maintaining an abundant and diverse microbial population as long as other elements of the cropping systems, including reduced or no-till, are also included. Incorporating a diversified cropping system can reduce the load of individual plant pathogens and adds new root systems that modify the microbial population of the rhizosphere. Differences in quality and quantity of organic residues returned to the soil from the various crops in a rotation and inclusion of organic nutrient sources help to enhance the soil organic content that reduced tillage can help maintain. This in turn can improve soil structure and structural resilience that will increase the capacity for exchange of nutrients and improve their efficient utilization.

Examples of managing AMF

Local indigenous communities of AMF are usually quite diversified, certainly well adapted, definitely cheaper and more efficient than commercial inoculum and form mutualist symbiosis with most cultivated plants. Furthermore, functional complementarity occurs within the AMF community colonizing a single root system (Jansa et al., 2008), and a more diverse population expands the opportunity of beneficial outputs. Practical examples of their management in agronomic systems have been described (Goss et al., 2017).

Prerequisites for managing AMF

Despite the complex relationships between crop production techniques, environmental factors and microbial diversity, there are clearly identified traits in the agronomic system that affect microbial performance. These include crop sequence, tillage regime or

fertilizers and manure amendments (Table 4, Fig. 4) that can be managed to define a strategy to promote beneficial microbial functioning. Identification of major concerns in a particular field, such as a prevailing stress for plant growth and nutrient supply, together with soil characteristics and cropping history, should be considered in defining appropriate strategies. Although current understanding is limited and the underpinning research insufficient, the management of microbial functioning in agricultural conditions should be considered in the context of sustainable agronomic practices. It must be consistent with natural ecological processes that include resilience of the system, more efficient use of inputs, and supporting long-term productivity.

Considering the issues associated with inoculation, a key aspect is to ensure colonization of the target crop by members of the indigenous AMF community. Potential sources are spores, colonized root fragments and ERM. Of these inoculum sources, ERM, when intact, commonly constitutes the most infective propagule by providing an earlier and faster AMF colonization, as documented both in pot experiments and agricultural ecosystems (Goss et al., 2017). Colonization started by an intact ERM optimizes the potential benefits from AMF to the host plant because it can capitalize on them sooner after exposure. This property of intact ERM is particularly important when crops are challenged by biotic or abiotic stresses existing in the soil at sowing, as the extent of AMF colonization at the time the host plant meets the stressor agent is directly related to the level of bioprotection achieved.

Given the preferential association between certain AMF and host plants, together with the characteristics of intact ERM as preferential inoculum, identifying a plant sequence and adopting reduced or no-till techniques are key components of a strategy that can ensure a consistent and predictable manipulation of the indigenous inoculum. It allows capitalization on the manifold benefits potentially provided by AMF and their functional diversity.

A possible strategy for the deliberate manipulation of the indigenous AMF population and its functional diversity consists of.

- 1 the intentional use of selected host plants to establish an extensive extraradical mycelium (Developer-plants) involving a consortium of the AMF,
- 2 keeping this ERM intact by the adoption of appropriate non-inversion tillage techniques,
- 3 support this preferential source of AMF inoculum to establish earlier and faster colonization of the following plant.

With this approach, effective protection has been achieved against abiotic (Mn soil toxicity) and biotic (*Fusarium oxysporum* or *Magnaportheopsis maydis* root pathogens) stresses in different host plants. Knowledge of the preferential association between AMF and a particular host plant (as Developer-plant) means that this strategy can also be used to manage AMF functional diversity (Brito et al., 2021). It can easily be applied at field scale in both low- and high-input cropping systems. The strategy may require adjustments to the cropping system, such as employing no-till or reduced tillage, selecting crop rotations or cover crops, that are easy to adopt and realistically can be implemented at a field level. Irrespective of other aspects needed to be considered (e.g., soil type and pH), choosing the Developer-plant involves specific criteria: for abiotic stress plants need to be tolerant of the stress, and representatives of the natural vegetation at the site provide the best opportunities for recruitment; for biotic stress the Developer-plant should not host the pathogen.

Abiotic stress

The ability of intact ERM to promote earlier and faster colonization and the efficacy of these strategies to protect wheat and subterranean clover plants against Mn toxicity was demonstrated in a two-phase pot experiment (Goss et al., 2017). Manganese toxicity resulted from the soil parent material and low pH. Unsterilized field soil was used, relying on a diverse indigenous population of AMF adapted to the conditions. The selected Developer-plants were annual ryegrass (*Lolium rigidum* L.) and yellow serradella (*Ornithopus compressus* L.), a legume, both highly mycotrophic plants. These plants were grown separately to develop the ERM. After 7 weeks, growth was stopped chemically with Glyphosate. The soil was undisturbed in half the pots of each developer treatment, the ERM was kept intact. In the remaining pots, the soil was disturbed and ERM disrupted by passing through a 4-mm sieve before being replaced in the same pots to act as a negative control. Two weeks later, an Mn susceptible crop, wheat (*Triticum aestivum* L.), was planted in half the disturbed and undisturbed pots of each Developer-plant treatment, and in the other pots subterranean clover was planted. Mycorrhizal colonization started earlier and developed faster, both in wheat and subterranean clover grown in undisturbed soil. Consequently, there was significant improvement in plant growth. There was no ability of AMF to protect plants against Mn toxicity in disturbed soil where intact ERM was absent.

When the AMF consortium forming mycorrhizal roots of a host plant has been formed from spores indigenous to the soil, each plant influences the choice of AMF in the assemblage (see Fig. 1. Note the similarity between consortia in wheat and annual ryegrass, and in yellow serradella and subterranean clover), and is usually consistent at the family level of plant taxa. However, when the consortium is formed from intact ERM associated with the Developer-plant, the AMF community present in the target plant shows a close relationship with the consortium in that plant (i.e., with that of the first plant of the succession, irrespective of its botanical group (Fig. 7, van Tuinen et al., 2017)). There is some evidence that the biochemical recognition dialogue between AMF and the host plant, which leads to a functional mycorrhiza, does not follow the same pattern but depends on whether the inoculum source is based on spores or intact ERM, as the plant symbiotic program depends to some extent on the colonizing propagule type. Gene expression by wheat was differentially activated according to the preceding Developer. The assemblage developed by yellow serradella activated processes in wheat related to cell division and growth, with only a few related to stress. However, when annual ryegrass was the Developer-plant, the wheat genes induced were those related to oxidative stress, disease protection and metal binding. It suggests that wheat genes activated by the consortium from annual ryegrass were less effective in protecting the plant from Mn toxicity than those activated by AMF from yellow serradella, which had a more positive effect on the shoot dry weight of wheat.

Fig. 7 Changes in taxonomic affiliation of the operational taxonomic units (OTUs) of AMF in a target or second plant in a cropping sequence, following colonization initiated by intact extraradical mycelium (ERM), are greatly influenced by the ERM-Developer involved. There are clear differences between the OTUs colonizing yellow serradella, subterranean clover and annual ryegrass grown following soil disturbance, with spores being the major form of propagule (top row). However, when yellow serradella (Fabaceae) or annual ryegrass (Poaceae) act as Developer-plants, and subterranean clover (Fabaceae) is the target or second plant, with intact ERM as the main propagule the AMF community present in the second plant shows a close similarity to that of the preceding Developer-plant, irrespective of its botanical group. Based on van Tuinen D, Brígido C, Brito I, Goss MJ, Alho L, and Carvalho M (2017) Cover plants, a tool to manage arbuscular mycorrhizal fungi diversity? 9th International Conference on Mycorrhiza. 30th July– 4th August 2017. Prague, Czech Republic. P(ID 384), pp 88.

Biotic stress

The effectiveness of AMF colonization in bio-protection has also been reported in relation to biotic stresses. Its success is frequently associated with AMF inoculation before the presence of a pathogen infection. Such observations indicate the need for well-established colonization prior to contact with the stressor agent. This apparent limitation can be overcome if AMF colonization begins earlier, which occurs when it is initiated by an intact ERM. Warm temperatures together with irrigation make spring or summer crops particularly vulnerable to biotic stresses, especially when monoculture is practiced over long periods. Under these circumstances the bio-protective role of AMF can also be brought to the cropping system by adjusting management practices. A judicious choice of over-winter cover crop, which can also function as a developer for ERM and maintain ERM integrity using appropriate land preparation, can be combined in a realistic bio-protection approach. Such an approach has already been tested in tomato (*Solanum lycopersicum* L.) and maize.

For field-grown tomato at risk from *Fusarium oxysporum* wilt disease, the modified production system adopted barley as the cover crop and an Developer-plant. Intensive deep tillage in spring was moved to the immediate post-harvest period and planting beds prepared, after which barley was sown. In spring, the Developer-plants were killed with systemic herbicide, planting beds had minor adjustments, and the tomato crop planted. The combination of cover crop and shallow soil disturbance resulted in significantly greater arbuscular colonization of tomato and less plant mortality from fusarium wilt, compared with a control area where standard practices were retained. Tomato production increased by 20 t ha⁻¹ - a 20% increase in total fruit production. In addition, an increase in general indicators of soil microbial activity (phosphatase, β -glucosidase, arylsulfatase, and urease activity) were also observed, underlining the beneficial effect of these practices on the general soil microbial population.

The same strategy was tested under field conditions for the bioprotection of maize against the soilborne fungus *Magnaportheopsis maydis* (was *Cephalosporium maydis*). The Developer-plant selected was Italian ryegrass (*Lolium multiflorum* L.). Tillage by moldboard ploughing and disking was compared with no-till. The presence of the soilborne fungus in maize was assessed by quantitative polymerase chain reaction. Only when a cover crop was grown and no-till adopted was there a significant reduction in *M. maydis* in the maize crop, which also resulted in greater dry matter production and a 19% increase in grain production (Patanita et al., 2020).

These examples demonstrate the ability to manage the indigenous microbiology and to use it to achieve a biological solution to soilborne diseases, for which no chemical option was available.

Complex interactions – the case of Mn toxicity in legumes

Subterranean clover shows little evidence of susceptibility to Mn toxicity when its N is obtained from mineral-N sources. However, the effects of Mn toxicity develop when plants become dependent on N₂-fixation in root nodules by the symbiotic diazotroph *Rhizobium leguminosarum* bv. *trifolii*. Hence, managing AMF to protect subterranean clover against the abiotic stress posed by Mn toxicity probably depends on the response of nodule bacteroids, or on both them and the plant. Using intact ERM as the preferential source of inoculum, Mn concentration in the roots was less, shoot and nodule dry weight, and N₂-fixation were greater than when other propagules were used. This is consistent with the hypothesis that better growth of the plant depended on protecting the rhizobia in the root nodules from the adverse effects of Mn. In this case, the interactions among participants in the tripartite

symbiosis have significantly increased the proportion of Mn uptake that was distributed to the shoots, maintaining the tissue concentration there, but reducing that in root tissue to overcome the inhibition of N₂-fixation. The efficacy of protection by AMF depended on the timing of early colonization events by both symbiotic microbes due to their use of common transduction pathways. Against this abiotic stress, there was little difference in effectiveness between the natural soil spore content and a combination of the spores and infected root fragments (Goss et al., 2017).

Conclusions

Soil contains a large number of microbes, with bacteria, archaea, algae, fungi, protozoa and small-size animals such as nematodes contributing the majority of individuals. These organisms participate in a wide array of processes in soil that affect the growth and development of the plants and animals that inhabit each locality, as well as contributing to the major geochemical cycles.

Given the numbers and wide range of soil organisms there are clear challenges to any attempt at directing their collective activities. Furthermore, their importance for soil and ecosystem functioning makes manipulation a potentially risky endeavor. Approaches to changing the composition of the microbe population are limited and either involve the addition of an inoculum of specific microbes taken from a different habitat, or modifying conditions such that particular components of the soil microbiome are stimulated. There is uncertainty in the effects, safety and reliability of inoculation as a general approach for extensive application, except where the local indigenous population has been lost. The evidence points to adopting agronomic practices as the main tools of manipulation. Tillage can be detrimental to balanced ecosystems but can be used to reset the system. Appropriate cropping systems can be used to attract and enhance specific groups of organisms into the rhizosphere where an effective rhizobiome can develop. In addition, the ERM of mycorrhizal fungi also harbor a distinct mycorrhizosphere community that are important in the functioning of the mycorrhiza. Thus, the development of a strategy for managing AMF can also influence other microbial components associated with the plants linked in a common ERM network. The strategy described for integrating bio-protection and other beneficial roles of native AMF into cropping systems, uses a Developer-plant for establishing ERM, which can be derived from numerous species. That ERM acts as the immediately available propagule for the colonization of crop plants that may be susceptible to biotic or abiotic stresses in the soil. Implementing such a strategy is versatile, requiring selection of the Developer-plant within the cropping system, potentially including common weed species, and ensuring, by adopting appropriate tillage systems, that the ERM developed is kept intact prior to the planting of the target crop. Increased knowledge of the functioning of rhizo- and mycorrhizosphere organisms is essential to future developments in soil microbe management.

Abstract

Soil microbial communities are critical for provision of above-ground ecosystem services, supporting biodiversity and regulating material exchange between earth and atmosphere. What is less evident is the importance of trees and shrubs in sustaining soil microorganisms. We consider system interdependencies between agricultural soils, plants and microbes, demonstrating negative effects of historic removals of woody vegetation from the landscape for the sustainability of soil microbial diversity. In contrast, reintroduction of shrubs and trees to agricultural systems, including agroforestry and hedgerow planting, has potential to restore soil functioning and create space for nature while offering many other benefits such as economic diversification and increased climate resilience.

Key points

- Trees, hedges and agroforestry play a critical role in sustaining soil biodiversity and terrestrial ecosystem services
- Removal of trees and hedges, under pressure from intensive agriculture and industry, has negative consequences for soil functioning
- As multifunctional landscape features, hedges and agroforestry create space for nature above and below ground while allowing space for economic use of land
- Although research has considered ecosystem service changes in large and complex landscapes, there is much less focus on small-scale aggregated benefits, synergies and trade-offs impacting soil functioning and practitioner decision-making

Introduction

Soil microbial communities contain a substantial majority of Earth's biodiversity. This abundant and largely hidden group of organisms is critical for both soil system functioning and the delivery of a wide range of above-ground ecosystem benefits. Soil microorganisms support life both above and below ground, providing energy, timely nutrient supply and a stable growth medium for plants, among many other ecological benefits.

The importance of well-functioning soil systems for the growth of plants is intuitive. What is less apparent, however, is the reverse: the critical role that trees, hedges and their roots play in supporting microbial diversity. In doing so, vegetation in the landscape indirectly sustains many of the benefits attributable to microorganisms. Understanding this interactive relationship requires a system-level view of the interdependencies between soil, microbial communities and vegetation. This chapter considers how the presence (and removal) of trees, hedges, and agroforestry influences microbial diversity, and the potential for the reintroduction of perennial woody vegetation to revitalize soil function, and simultaneously bring systems of economic production on land back in step with biosphere interdependencies. We first consider interdependencies which exist between vegetation and soil microbial communities, focusing on trees and hedges and the consequences of their removal for whole system functioning. Then we consider how hedges and agroforestry, as intentional and multifunctional landscape features, may support and restore the health of below-ground systems. This may be direct, via rhizosphere effects, and indirect, through effects on hydrology and microclimate. We conclude by summarizing the potential for planting strategies to generate change for soil systems and priorities for further research.

Soil microbes and system complexity

Microbial communities are integral to soil function, responsible for mineralization and cycling of nutrients within soil, as well as controlling both formation and decomposition of soil organic carbon (SOC). Abiotically, microbes contribute to soil structure and formation of aggregates, and the formation and transformation of organic matter (OM) (Prescott et al., 2019). Soil supporting services such as nutrient availability and water holding capacity are thus substantially mediated by microbial activity (Dollinger and Jose, 2018). Plants receive material benefits from microbial communities such as timely nutrient supply and reliable soil water access. Associations with mycorrhizal fungal networks improve nutrient supply and resilience against drought by increasing root-hyphal surface area. These networks protect against pathogens both physically and by production of signaling compounds that can induce a coordinated defense response in the plant community (Prescott et al., 2019). The centrality of these interactions means that soils are widely considered to be degraded once microbial activity is suppressed, unable to offer supporting ecosystem services vital for life.

Organic matter drives the soil food web, and the majority of soil microbes rely on carbon as a source of energy. Approximately 1500 Gt of the organic matter stored in the top meter of global soil is carbon, and this chapter will focus on this critically significant component of the terrestrial ecosystem. SOC is statistically correlated with other indicators of soil function, particularly aggregation, soil formation, and water holding capacity (Shukla et al., 2006). SOC is a significant reservoir in the context of sustainability more widely, both for soil fertility and maintenance of microbial diversity, but also wider public goods such as resilience of food and climate systems, resistance to desertification and protection of global biodiversity both above and below ground. Yet since the onset of ancient agriculture and widespread land-use change for cultivation, large quantities of C have been lost from the world's soils. SOC losses have received particular attention due to implications for climate and impacts on soil fertility for agriculture. It is estimated that 133 Gt C has been released to the atmosphere as carbon dioxide (CO₂) through land-use change with a particular acceleration in the last 200 years (Sanderman et al., 2017). Land-use change has produced wider soil impacts, including greater propensity toward drought, salinization, acidification, compaction, nutrient depletion, and soil losses through erosion. Impacts on soil structure have arisen both through SOC losses and physical disturbance: practices such as frequent tillage or intensive grazing degrade structural elements of the soil, including physical alteration of soil aggregates and collapse of macropores, resulting in compaction. Disturbance alters soil habitat for both smaller and larger soil organisms, eventually diminishing below-ground functional diversity and the ecosystem services which are sustained by soil. Plant-mycorrhizal symbioses are consequently affected, and soil microbial respiration rates increase once SOC stabilized within soil aggregates or as mineral-associated organic matter is exposed to decomposition by organisms.

Negative outcomes of land-use change collectively impact soil microbial communities. However, individual negative outcomes are not produced in isolation, and significant interdependencies exist within the terrestrial ecosystem (Fig. 1). For example, reduction of SOC stocks diminishes available energy for organisms; as soil microbial biomass is consequently diminished, the ability to provide supporting services to vegetation is weakened (Fig. 1, R1). Yet removal of vegetation, or reliance on external sources of nutrition, in turn impacts microbial communities. SOC stocks are commonly in a dynamic equilibrium between removal via metabolic respiration by soil organisms (as CO₂) and inputs such as plant litter, root material and C-rich exudates produced by trees and other plants to regulate the soil environment in the vicinity of their roots. Forests, trees, shrubs, and grasslands are all examples of perennial vegetation which return litter and exudates to soil in this way. Once they are removed, the rate at which C is photosynthetically fixed and transferred to the subsurface is likely to be diminished, reducing available energy for soil microorganisms. Annual crops planted for agriculture in place of perennial vegetation fix and transfer some C to the soil, yet the process is significantly weakened in comparison. Wheat roots, which cease growth by early June in the northern hemisphere, transfer less than half the C to soil annually compared with perennial grass-clover ley. Trees, shrubs, and forests return considerably more even than perennial grasses due to their deeper roots and more abundant litter. Thus, removal of crop biomass at harvest, frequent tillage and lack of biological diversity in agricultural landscapes all reduce net C fluxes into soil systems. Reduction in C inputs to soil is a problem because negative plant-soil feedbacks are generated, whereby disrupted C supply to soil microorganisms diminishes their ability to make nutrients available to plants, which in turn inhibits growth and further C addition. Similarly, exudation benefitting soil microorganisms is energetically expensive for plants, such that they are potentially less likely to produce exudates in exchange for nutrition if nutrition instead comes from synthetic inputs. Studies have demonstrated the negative feedbacks that management choices such as tillage and agrochemical use have on plant-soil feedbacks (Menalled et al., 2020).

Further complex feedbacks arise elsewhere in the soil system. Both reduction in SOC stocks and compaction resulting from soil disturbance decrease soil water holding capacity. More compact soil has less available pore space, such that water infiltration can be reduced, and surface runoff increased, resulting in greater erosion risk and removal of C-rich habitat from the top soil. Meanwhile, removal of trees and shrubs, or other vegetation, leads to physical exposure of soil, making it vulnerable to disturbance. Disturbance, in turn, exposes SOC to decomposition by microorganisms, depleting C stocks and releasing CO₂ to the atmosphere.

What is evident from these interactions is that no component of the system can be considered in isolation. Disruption to one component produces unintended consequences elsewhere. Consequences may be reinforcing (R) or balancing (B), as shown in Fig. 1. For reinforcing feedbacks, gain or loss of system function will be exponential, whereas changes to balancing feedbacks set new equilibrium points for the system (Meadows, 1999). Within undisturbed forest soils, interactions in the soil system are remarkably circular—leaching beneath forests is very small in comparison to large internal fluxes within the plant-soil system itself (Prescott et al., 2019).

Trees, shrubs, and soil biodiversity

Interactions between plants and soil microorganisms in natural ecosystems can be mutually beneficial, harmful or simply neutral (Lynch, 1990). Plant species produce exudates from fine roots, with which they regulate the soil environment surrounding roots and microbial dynamics within it. The rhizosphere (Fig. 2), in its earliest definition, refers to the volume of soil surrounding living roots which is influenced by root activity (Hiltner, 1904; Haichar et al., 2014), into which between 5% and 21% of photosynthetically fixed C is transferred through root exudates (Whipps, 1990). Rhizodeposition is a broader term incorporating not just exudation but also deposits of root hairs, fine branches, border cells, and other cells from the root cap and epidermis into soil surrounding plant roots. It enables the plant to cope with herbivores and parasites, changes the physical and chemical properties of soil and inhibits the growth of competing plant species (Haichar et al., 2014) (Fig. 2). Exudates include amino acids, organic acids, sugars, and other secondary metabolites which are released into the soil through passive diffusion from roots.

A steep concentration gradient of these exudates exists as they are swiftly consumed by microbes in the vicinity of roots. Secreting C-dense exudates is costly to the plant in terms of energy, yet in return microbes make soil nutrients accessible to plants in a timely manner for growth. Exudate composition is plant species-specific, allowing plants to attract and recruit a range of beneficial microbes from bulk soil in addition to modification of soil structure and resisting pathogens. Exudates change according to the growth stage of plants, and plant-soil interactions are active, in that plants recognize and actively respond to different microorganisms within the rhizosphere. Beneficial interactions occur with rhizobia, mycorrhiza and rhizobacteria, including protection for plants against both biotic and abiotic stresses. Negative interactions occur with parasitic plants, pathogenic microbes, and invertebrates (Fig. 2) (Haichar et al., 2014). The consequence of these interactions is that the rhizosphere has distinctively different chemical, physical and biological characteristics to soil outside the rhizosphere.

The complexity and diversity of interactions within the rhizosphere illustrates the importance of woody vegetation and roots for the functioning of soil systems. Although globally the C stock of terrestrial vegetation is smaller than that of soils, vegetation is nonetheless critical in regulating exchange of material between soil and atmosphere. Trees and woody vegetation regulate soil microbial communities through their control on exchange of C, water and other nutrients between pedosphere and atmosphere, and abiotic management of soil structure. Above-ground biodiversity interacts with below-ground habitat to promote soil functioning. Although the precise mechanisms of material exchange remain are yet to be fully characterized, it may be presumed that when ecological systems are diverse, the rhizosphere is permitted to function as normal, sustaining feedbacks which lead to a thriving and resilient soil system capable of delivering multiple benefits (Aislabie and Deslippe, 2013). Indeed, in arable systems, taxonomic diversities of key species of arbuscular mycorrhizal fungi have become reduced compared with woodland systems, implying impaired soil system functioning (Helgason et al., 1998). The removal of woodland, forest, hedges, and native grasslands across the world to make way for agriculture has substantially impaired interactions between above and below ground systems, with negative implications for sustainability and soil functioning. The reintroduction of trees and shrubs and other forms of biodiversity in the landscape is thus critical in sustaining soil microbial communities.

Fig. 2 Examples of rhizosphere interaction between plants, soil and soil microorganisms.

Hedges

Species-rich semi-natural and natural habitat remnants play a key role in maintaining biodiversity as well as delivering a range of other ecosystem services in agricultural landscapes (Table 1). Hedgerows are an example of such habitat—linear features composed of shrubs and trees that were traditionally planted to delineate fields, simultaneously providing stock-proof boundaries, as well as being sources of food, fuel, and timber. Increases in population density, intensifying competition for productive land and mechanized farming produce a need for delineation of holdings and systems of management such that useful space is maximized and tools or machinery may be used as efficiently as possible. Hedges have been effective in this regard, not only providing linear separation and efficient use of space, but also other ecosystem benefits such as space for nature within cultivated landscapes. However, after the Second World War, farmers in many countries were encouraged by policy and financial incentives to remove hedgerows to make farming even more efficient, incorporating bigger farm machinery and goals of greater food self-sufficiency. At its peak, hedgerow removal in the United Kingdom reached 6400 km per year. Hedge removal produces negative impacts for biodiversity and wider ecosystem service delivery. Given that hedges can trap large quantities of sediment moving downslope during storm events, removals can lead to sediment loss from agricultural landscapes, with associated deterioration in downstream water quality. In the EU hedge systems have made way for growing agricultural operations since 1990, resulting in less space for nature and increasing ecosystem damage, such that European agricultural areas are among the most ecologically degraded of all habitat types on the continent (Pe'er et al., 2014). Restoration of hedges is thus a policy priority in many temperate zones, particularly where hedges are simultaneously capable of providing space for nature without substantial encroachment on agriculturally productive land.

Extensive hedge networks are commonly found in temperate landscapes. A well-known example is the bocage of northwest France (Fig. 3), although hedge networks are also common in the United Kingdom and across much of Western Europe. Hedgerows enhance ecological corridors for biodiversity, protect soil and limit wind and water erosion. Soil carbon storage is enhanced, flood risk may be reduced in some circumstances and hedge networks offer considerable landscape amenity. Soils under hedge systems are more enriched in organic matter than the fields they surround, resulting in lower bulk density, higher infiltration rates and increased vertical drainage. N uptake in the vicinity of hedges may also be enhanced, improving water quality. Large canopies facilitate higher interception while demand for water and deeper roots under hedges increase evapotranspiration, resulting in drier soil. This, in-turn, reduces the development of saturation-excess overland flow, maintaining subsurface storage capacity for storm rainfall and incoming flows from upslope. Water tables below hedgerows are commonly depressed compared with adjacent fields, and the uppermost soil layer is likely to contain significantly less moisture than adjacent grass margins, pasture or arable fields. Hedges may influence soil water content in winter up to 10 m on either side due to the hydraulic gradient generated by drier soil in the vicinity of roots (Caubel et al., 2003; Holden et al., 2019). Scaling up hydrological effects such as these from field to whole catchments is challenging—once separate drainage systems are combined, the complexity of interactions between flow processes increases to such an extent that it becomes very challenging to model the impact of hedgerows on landscape flood mitigation. Nonetheless, evidence illustrates the importance of hedge soils as a valuable sink for excess water to mitigate downstream flooding particularly when hedges are aligned across-slope, reducing sediment loss from agricultural fields during storm events and loss of soil habitat from within catchments.

Whereas the above-ground landscape benefits of hedges are more visible, effects on below-ground soil functioning are much less well known. However, hedge soils show very different characteristics to either conventional or even organic fields. Fungal biomass and diversity are elevated beneath hedges due to the lack of fungicide applications and extra plant diversity. Fungal populations are capable of decomposing recalcitrant organic compounds which are prevalent beneath hedge soils. This means that hedge soils are commonly fungal-dominated, unlike soils which receive high inputs of synthetic fertilizer or are beneath monocultures which are typically bacterial-dominated (Bardgett et al., 1999). Hedge soils and grassy field margins typically support more diverse communities of macrofauna such as earthworms, which can be 1–2 orders of magnitude more abundant than in adjacent fields. Hedge soils store a third more C in the top half-meter than beneath intensively managed grassland, and can accumulate C at a rate of 1.5 Mg C ha⁻¹ yr⁻¹. Soil temperatures are additionally better regulated, although curiously the drying effect of soil beneath hedges can give rise to higher solute concentrations of NO₃⁻ and PO₄³⁻—a counterintuitive result given the lack of fertilizer applications beneath hedges (Holden et al., 2019; Biffi et al., 2022).

The relative complexity of soil systems beneath hedges, in contrast to conventionally cultivated areas, generates habitat for subsurface diversity to drive enhanced soil functioning and ecosystem service delivery. Enhanced agroecosystem complexity in landscapes with hedges is correlated with many beneficial factors in the vicinity of hedges, such as increased stocks of SOC, which in turn supports a more dynamic microbial population. The reintroduction of hedge ecosystems is becoming a priority for governments including both the UK and EU countries, as reports increasingly recognize the role that hedgerows can play in achieving biodiversity gain and net zero targets on land. What remains to be seen is whether hedge systems alone can reinvigorate soil system functioning at sufficient scale for benefits to have a landscape effect and deliver on both economic and ecological goals.

Agroforestry

Agroforestry is the cultivation of two or more species of plants (or plants and animals) within the same space, at least one of which is a woody perennial (Nair, 2004). Agroforestry thus offers many of the same benefits as hedges, such as shelter and protection of soil,

Table 1 Contributions of trees, hedges, agroforestry, and soil microbial communities to ecosystem services.

<i>Ecosystem service</i>	<i>Description</i>	<i>Soil microbes</i>	<i>Trees, hedges, and agroforestry</i>
Raw material	Soils have historically been used as raw materials, e.g., as peat for fuel or as building material (rammed earth, bricks)	Microbes contribute to soil formation through nutrient cycling and organic matter production	Timber trees offer wood as a building material, and short rotation woody crops may be grown for bioenergy
Promotion of vegetation	Vegetation and associated products are used in many contexts including as food, energy and building materials. Plants consequently provide services of their own, such as carbon cycling, filtration and public amenity	Soil microbes make otherwise sparingly soluble nutrients, such as Fe and P, available to plants to support growth	Hedges and agroforestry create shelter, allowing plants to be established in their vicinity
Natural flood management	Storage of excess water in the landscape may alleviate flood risk following extreme precipitation events; degree of storage is mediated by soil structural variables such as bulk density, infiltration rate and permeability, and surface understory variables influencing surface roughness interactions with overland flow	Soil microbes directly influence soil structure, and are additionally a food source for ecosystem engineers such as earthworms, responsible for formation of macropores. Microbes support plant roots and their contribution to soil structure	Soils under hedges and agroforestry demonstrate higher levels of infiltration, allowing water to be stored in the landscape during storm events, mitigating downstream flood peaks at local scales. Additionally, tree and hedge canopies intercept water, creating above ground storage reducing flood peaks
Nutrient cycling	Soil cycles nutrients by facilitating decomposition of organic matter and mobilizing bedrock and aggregate material	Soil bacteria, archaea and fungi drive nutrient cycling in soils and are involved in weathering minerals	Leguminous trees and shrubs are capable of fixing N from the atmosphere in soils
Waste recycling and detoxification	Soils absorb, detoxify and recycle waste materials, agrochemicals and fuel or oil spills, reducing environmental hazard	Microbial mineralization and immobilization processes mitigate the effects of pollutants. Microbes are the main way that organic pollutants are degraded in soil	High transpiration rates, root biomass and longevity allow perennial vegetation to process waste through phytoremediation
Filtration of contaminants	Leached materials such as synthetic fertilizer may contaminate streams and lakes and their ecosystems. Soils act as a buffer, absorbing contaminants within clay minerals and organic matter	By contributing to soil physical structuration and the wider soil food web, microbes promote water holding capacity of soils and their potential to absorb contaminants. Mycorrhiza reduce the leaching of mineral nutrients	Trees and plants absorb atmospheric pollutants including those harmful to human health, removing them from the environment
Natural habitat	Although comparatively less well studied, soil is home to an enormous proportion of global biodiversity which itself depends on natural soil function for survival	Soil bacteria, archaea and fungi comprise the vast majority of global biological diversity, while also being the foundation of soil food webs and underpinning higher trophic levels both above and below ground	Trees and hedges provide essential habitat for above ground biodiversity and ecological corridors in the landscape. Additionally, roots create habitat for below ground microorganisms and fungi
Control of pests, weeds and pathogens	By providing habitat for beneficial species capable of managing pest populations and pathogens, soil provides a buffer against invasive species	Many beneficial species are soil microbes which support plant growth and manage populations of pathogens	Trees manipulate the soil environment in the vicinity of roots (rhizosphere) using exudates. This includes control of pathogens and competing plants and herbivores
Regulation of greenhouse gas emissions	SOC represents the second-largest deposit of C after the oceans, making soils a significant influence over global greenhouse gas concentrations including CO ₂ and CH ₄	Soil microbes both mineralize and decompose soil C and other nutrients, thus influencing both the C storage capacity of soils and rates of exchange of greenhouse gases with the atmosphere	Woody plants absorb CO ₂ for photosynthesis. C is sequestered in the form of above ground biomass, and also transferred to soil through leaf and root litter, and as C-dense exudates from roots

while substantially increasing the density of space for nature in agricultural land. Consequently, agroforestry systems are more complex, both ecologically and economically. Within agroforestry systems, trees may be planted both on the edges of fields and in among productive areas normally used solely for livestock or annual crops.

The first written use of the term *agroforestry* was in the late 1970s, at which time the focus was explicitly on provisioning benefits of incorporating trees into farming systems, only alluding to sustainability as a secondary benefit in service of provisioning. However, such a focus is not unusual; practices resembling agroforestry are ancient, and the productivity benefits of farming with trees have been known for millennia. Throughout history crops and trees have been deliberately cultivated together, and like other regenerative or agroecological practices, agroforestry can be found in ancient indigenous practice (Nair, 1993). Practitioners of agroforestry often do not use a word to describe it, instead considering simply normal or traditional practices. The Yoruba of Nigeria cite soil fertility and avoidance of nutrient leaching and erosion as principal benefits of combining herbaceous, shrub, and tree crops (Nair, 1993). Shade-grown coffee and cocoa comprise a considerable area of global agroforestry, and for many years communities have identified better food security and economic returns as reasons for combining the two crops. Similarly, some of the most successful examples of agroecological farming today revive ancient technologies, incorporating trees to promote productivity and simultaneously conserve resources, with potential to reclaim function within partially or wholly degraded soils otherwise unsuited to sustainable production.

More recently agroforestry has been defined simply as ‘farming with trees’ (Soil Association, 2019). Particularly in the industrialized world, the stated environmental benefits of agroforestry have grown in prominence as an alternative to conventional, intensive land management systems. Overreliance on agrochemicals such as fertilizers and pesticides and the systematic conversion of natural habitat to cultivation have detached agricultural practice from ecological cycles which sustain ecosystem service provision. Yield and efficiency gains through the 20th century, although economically significant, are not sustainable so long as natural systems simultaneously sustained by land are neglected. In contrast, the presence (or reintroduction) of trees on farms offers potential to restore and take advantage of ecological complexity for the benefit of provisioning and ecosystem regulation. In this sense, agroforestry is typical of agroecological methods, applying ecological principles to the design of food systems (Gliessman, 2014) and utilizing circularity to generate multiple benefits and simultaneously address challenges to soil functioning, food security and environmental sustainability.

For most of history, food production has been the justification for incorporating trees on farms, with ecological gains serving that purpose. The potential for agroforestry to deliver global goods beyond provisioning, in particular carbon sequestration or resilience against climate change, is comparatively modern and part of the growing trend in its popularity. Of particular relevance is the extent to which agroforestry can deliver benefits in temperate regions to mirror its success elsewhere (e.g., tropics) for both people and environment. Historic agroforestry practices are found in temperate areas—the concept of ‘dehesa’ (Fig. 4), a Spanish system (‘montado’ in Portugal) in which dispersed pastureland is interspersed with holm and cork oaks, has origins in the early Middle Ages, however the practice is almost certainly much older than the word (Álvarez, 2016). Similarly, trees planted within slash and

burn systems in Germany date back to the Middle Ages. Lines of trees have often historically been introduced as shelterbelts, and some modern agricultural landscapes in Europe resemble agroforestry simply as a result of remnant trees surviving land-use change. What distinguishes modern agroforestry from the simple presence of trees on farms is its intentionality and focus on people and management as integral components of the system.

Agroforestry includes several subdivisions depending on system design (Fig. 4). Silvopasture describes integration of trees with livestock such as ruminants, pigs, or poultry, an example being the dehesa or montado system mentioned above. Silvoarable agroforestry is the integration of trees and crops in the same field. Within silvoarable systems, trees are normally planted in rows to allow access for machinery, with crops in the 'alleys' in-between; as such silvoarable agroforestry is often referred to as 'alley cropping' (Lawson et al., 2016; Soil Association, 2019). Additionally, all three elements (trees, crops, animals) may be combined into an agrosilvopastoral system. Additional systems are commonly classed as agroforestry: shelterbelts, windbreaks and riparian buffer strips may also be examples of trees on farms for the promotion of ecosystem and economic benefit, designed to protect livestock, crops or soil and water quality. Smaller-scale applications such as kitchen gardening make use of trees to contribute to vegetable production.

The reintroduction of trees to farmed landscapes in more recent times is thus with the explicit focus of strengthening soil function and wider ecosystem goods lost through land-use conversion to conventional agriculture. Trees provide ecological

corridors within the farmed landscape, while offering many of the benefits for soil function that come with increased diversity of vegetation and the ability to host higher levels of above and below ground biodiversity.

Introduction of conventional broad-leaved woodland (>400 stems ha^{-1}) on previously arable land generally delivers higher long-term SOC stocks in soils. Other soil function benefits can emerge in tandem with C improvements, such as increases in plant-available N, earthworm abundance and functional diversity (Ashwood et al., 2019). Planting densities for agroforestry are typically lower ($75\text{--}200$ stems ha^{-1}) than for woodland, yet enhanced SOC stocks are nonetheless commonly observed to a depth of 100 cm. The effect is dependent on the type of land-use change; combining global studies illustrates that conversion from arable to agroforestry produces the largest increase in SOC stocks ($+40\%$), with a much smaller increase for converting pasture or grassland to agroforestry ($+9\%$) (De Stefano and Jacobson, 2018). Agroforestry systems have larger SOC concentrations than treeless control sites (both diachronic, in which controls are baseline-sampled on the same site before agroforestry establishment; and synchronic, in which controls are a treeless neighboring plot with similar characteristics). Broadleaf systems lead to greater SOC addition than coniferous systems, and hedges lead to the greatest addition of SOC to soils in comparison with treeless or hedgeless sites, followed by silvoarable and silvopasture sites, respectively (Mayer et al., 2022).

When we consider agroforestry and SOC effects more closely in context, the picture becomes more complex. Evidence from a number of sources suggests the importance of understory vegetation in controlling SOC beneath trees and grassland. Fine root density is generally higher where understory vegetation is dense and thriving, which may in turn lead to higher rates of rhizodeposition and incorporation of root matter into the soil, elevating SOC concentration. Particularly for silvoarable systems, it is possible that the majority of above-ground organic C inputs come from herbaceous vegetation, and not from trees, and similarly when understory is absent or artificially eliminated, SOC stocks beneath agroforestry are commonly reduced. At a simple level, inputs of C to the soil come via three principal pathways: addition of leaf litter (or pruning residue) to the soil surface, addition of fine root litter within the soil and the production of organic carbon exudates within the rhizosphere (see Fig. 1). SOC stocks in soil are in a dynamic equilibrium between gains from exudates and organic matter, and two types of loss: firstly to the atmosphere as CO_2 as a result of decomposition, and secondly via the aquatic ecosystem through leaching of dissolved organic carbon (DOC) or erosion of particulate organic carbon (POC). Root matter helps to stabilize soil aggregates, which in turn protects organic molecules from exposure to microbial breakdown and loss from the system.

Interactions between trees and soil with respect to macronutrients are well known in tropical zones. For example, the addition of leguminous (N-fixing) trees in agricultural systems has been shown to improve circularity in N usage. Trees and crops compete for N in the surface soil in tropical soil systems; however, tree roots access leached N from deeper soil horizons otherwise inaccessible to crops and their more superficial rooting systems in a process known as nutrient 'pumping.' Alfalfa (*Medicago sativa* L.) used as an N-fixing intercrop within alleys of 17-year-old walnut trees (*Juglans nigra* x *Juglans regia* L.) in a Mediterranean experiment show that yield losses in shaded areas close to tree rows are buffered by facilitative mechanisms between plants and trees which increase light use efficiency in the intercrop (Querné et al., 2017). Moreover, agroforestry systems can add nutrients to surface soil directly through litterfall. In Zambia *Faidherbia albida* A.Chev., an N-fixing tree, is used to improve soil fertility in the short term. Soils amended with *F. albida* leaf litter demonstrate greater rates of N mineralization than control soil samples with fertility boosted beneath the canopy through longer-term modification of soil biological and chemical properties (Yengwe et al., 2018).

Physical canopies of trees create a microclimate for below-ground organisms, with some mature species hosting 35%–60% more microbial biomass C in soil beneath their canopies. Litterfall leads to extra soil fertility, but canopies also create habitat for larger animals such as birds whose fecal matter is added to soil beneath trees. Trees modify the soil environment for microorganisms through the effect of roots and canopies on catchment hydrology. By increasing SOC stocks, afforestation of mineral soils produces greater soil water holding capacity and infiltration capacity during storm events. By creating subsurface habitat for soil microorganisms and other ecosystem engineers, trees promote physical alteration of the soil structure and the formation of macropores and channels. These in turn promote lower bulk densities for soil and alter hydrological functioning.

The litterfall effect may be moderated by tree age and, in turn, litter quantity. Younger cacao trees in an agroforestry site in Mexico moved a greater supply of phosphorous (P), calcium (Ca), magnesium (Mg), iron (Fe) and copper (Cu) into soil because they produce a higher supply of litter than older trees (Pérez-Flores et al., 2018). But irrespective of age, the trees are able to compensate for the nutrient demand of the main crop. Litterfall supply of each of N, P, Ca, Mg and also potassium (K) is sufficient to recover nutrient concentration lost to the main cacao crop, demonstrating the greater circularity in nutrient use which is typical of complex agroforestry systems.

However, species choice in agroforestry systems is critical for maximizing nutrient benefits. Facilitation of increases in stocks of different nutrients in soil can be species dependent, with several examples from experimental studies. Isolated trees in a Nicaraguan silvopastoral system increased C, N, and P concentrations in the topsoil, with *Crescentia alata* Kunth improving N stocks and *Guazuma ulmifolia* Lam. favoring P stocks (Hoosbeek et al., 2018). N mineralization patterns varied among 10 plant species considered by Partey et al. (2018), with greatest N-supply (up to 93 mg N kg^{-1}) coming from two of them—*Tithonia diversifolia* (Hemsl.) A.Gray and *Gliricidia sepium* (Jacq.) Steud.

Knowledge of nutrient effects in temperate areas is more limited, although species-specific effects nonetheless emerge. For example, roots with larger N and P concentrations, such as those from legume crops, promote a smaller C:N ratio which facilitates faster decomposition of organic matter; furthermore, additive effects between litter and crop residues enhance efficiency of uptake and grow long term fertility (Zeng et al., 2010). To an extent, trees compete with alley crops for nutrients, and seasonal phase effects between each are critical for overall efficiency. As if to demonstrate this, yields and N use efficiency for agroforestry systems may be influenced by the presence or absence of artificial barriers between tree and crop. In a US Midwestern maize system combined with

black walnut trees (*Juglans nigra* L.), tree roots take up soil water and N before the maize is planted, reducing supply for the crop. With a 1.2 m soil barrier in place the effect is minimized (Jose et al., 2000). Yet there are caveats: fine tree roots due to their more rapid release of N and P, are able to bolster soil nutrient pools. Additionally, the pre-existing nutrient-depleted state of the soils may create a dependency for artificial N input. With stronger positive feedbacks associated with fertility and microbial activity, such inputs could potentially be reduced.

Introduction of trees to agroecosystems creates habitat for wildlife and opportunities to improve ecological connectivity. By reconciling higher levels of production with greater species diversity, the potential exists for agroforestry to contribute to restoration of biodiversity in farmed landscapes. Among the most damaging impacts of intensive agricultural practice in the last century has been declines in insect pollinators. Yet silvoarable and silvopastoral systems are capable of increasing airborne arthropod diversity compared with monocultures. Bees and hoverflies may be found to be twice as abundant, seed set several times greater and species richness of solitary bees an order of magnitude greater within agroforestry systems, compared with monocultures (Varah et al., 2020). By restoring space for nature within cultivated landscapes, agroforestry systems are capable of supporting pollinators and beneficial pest predators.

Agroforestry, if deployed at scale, carries the potential to reconcile need for land for cultivation with a similarly critical need to sustain soil system functioning. Greater SOC and nutrient stocks benefit soil microbial dynamics, ensuring the food web is supported by a steady supply of inputs. As discussed, increased plant diversity is capable of promoting greater shoot and root biomass, quantities of exudates, bacterial biomass and fungal biomass—demonstrating once again the close linkage between above ground system complexity and below ground functioning. Explicit links between above ground biodiversity benefits and subsurface dynamics are limited, requiring a greater focus on the centrality of soil biodiversity in the sustainability of agricultural landscapes. But as with hedges, evidence strongly points toward a close relationship between agroforestry, landscape resilience, and holistic functioning of soil systems.

Summary

Trees and hedges are critical in supporting microbial diversity within soil systems. Systems with greater density of woody vegetation promote ecosystem benefits including greater SOC stocks, efficient nutrient cycling, reduced erosion and protection of soil habitat, while enhancing hydrological functioning. Ecosystem services sustained by soil microbial diversity are thus directly supported by perennial woody vegetation. Although we can infer characteristics of these linkages however, quantitative study of the pathways themselves is challenging. Crop studies are one means of understanding linkages and have shown that greater plant diversity leads to greater shoot biomass, root biomass, quantity of exudates, bacterial biomass, and fungal biomass. Yet it is difficult with this method to isolate growth directly attributable to rhizodeposition. Some have tried to overcome the issue in the field by using isotope tracers such as $^{14}\text{CO}_2$, yet the difficulty of accurate in-field measurement persists making quantitative identification of fluxes elusive. Growing plants hydroponically offers better visibility of interactions, albeit in an unrealistic environment. The exact pathways by which soil microorganisms are supported by vegetation thus still need to be uncovered. Nonetheless, interdependency between above-ground vegetation and microorganisms is demonstrated in the marked loss of functioning once land systems become dominated by monoculture or systems of land use which are more linear than circular. Effective stewardship of soil system resources requires an appreciation of their complexity and circularity, and the design of systems which operate in step with these interactions.

Although the benefits of agroforestry and hedge restoration may be characterized at large scale, practical considerations remain in terms of addressing constraints on implementation within local geographies. Firstly, better evidence is needed for ecosystem effects in temperate and boreal zones. For example, dynamics of nutrient cycling are better mapped elsewhere in the world, especially in the tropics, and these must be verified or adapted for temperate settings to design strategies for reintroduction of trees or hedges to agricultural landscapes. Secondly, an understanding of causal dynamics, system complexity, and feedback mechanisms within agroforestry systems would facilitate understanding of wider ecosystem goods and the consequences of particular interventions, particularly at catchment scale and above. This is particularly the case for flood management and hydrological effects, for which nonlinear dynamics become important when small-scale interventions are aggregated. Thirdly, and building on a complex systems perspective, better understanding is needed of the aggregated benefits, synergies and trade-offs associated with agroforestry interventions in the plot-scale spatial domain. High level effects of practices such as agroforestry on whole landscapes have received considerable attention, yet much less is known about effects on simultaneous multiple benefits at smaller scale, including soil functioning. The number of large-scale studies far exceeds the extent of local, reusable, and diversified scientific knowledge which can inform practitioners how to make instrumental changes at scales over which they have control. With this knowledge, decentralized action in the landscape capable of regenerating soil systems becomes a realistic goal.

Abstract

Urbanization coincides with direct and indirect anthropogenic impacts on soil health resulting in remarkable changes in diversity and functionality of soil microbiome. Soil sealing, pollution or salinization deplete soil microbial biomass and hamper microbial activity. Development of urban green infrastructures including constructing Technosols, introduction of new vegetation species, management and maintenance practices create favorable conditions for soil microbiome. Microbial indicators are very informative for urban soil monitoring and assessment since they reflect complex and diverse processes occurring in soil life phase in urban environment. Soil microbiome is sensitive to anthropogenic stressors, and dynamics in microbial properties is widely used to monitor anthropogenic and technogenic alteration of urban ecosystems. At the same time, ecosystem adaptation to these stresses is driven by mutual interactions and co-adaptation between soil microbiome and urban vegetation. This chapter reviews diversity of urban soils' microbial properties and explores climatic conditions, typology and composition of green infrastructures, management and maintenance as the driving factors behind microbial variability and functionality in urban soils.

Introduction

Soil microorganisms play a crucial role in all terrestrial ecosystems as they form a vast reservoir of genetic diversity and make a substantial impact on soil forming processes and functions. Soil is home for a diverse array of microorganisms including bacteria, archaea, microscopic fungi, and viruses. The whole complex of these microorganisms is called the soil microbiome and supports important soil functions and ecosystem services, such as organic matter mineralization (Li et al., 2018; Liu et al., 2022), regulation of nutrient cycling (Basu et al., 2021), biodiversity (Berg et al., 2017), biodegradation of pollutants (Diakhaté et al., 2016) and climate regulation (Joergensen and Emmerling, 2006).

Urban ecosystems are influenced not only by biotic and abiotic environmental factors, but also by human activities, which change soil composition and lead to high heterogeneity (Yang and Zhang, 2015). The impact of these activities on the soil microbiome is complex and can be influenced by a variety of factors, including urbanization intensity, soil properties, land use and management practices, as well as the level and type of pollution, and the presence of green infrastructure (Wuyts et al., 2020; Gómez-Brandón et al., 2022). The spatial structure of soil microbial communities can be affected by numerous factors, both direct and indirect. Soil pH, nitrogen availability, soil organic carbon content, temperature, and redox status are likely the most significant factors that can have a noticeable impact on the structure of soil communities (Pett-Ridge and Firestone, 2005; Cederlund et al., 2014).

Urban soils have been found to harbor a diverse range of bacterial and fungal microbial communities that play a crucial role in supporting green infrastructure such as parks, green roofs, and bioswales. These microbial communities contribute to enhanced functional potential in nutrient assimilation and cycling, bioremediation, and decomposition, which collectively enhance the overall health and resilience of urban ecosystems (Gill et al., 2020).

Soil microbiome of each city represents a complex, diverse, and dynamic system influenced by numerous factors, including climate, local environment conditions, land use patterns, industrial development, and the level and type of pollution. Anthropogenic activity resulting in contamination with oil, polychlorinated biphenyls, cement dust, or household waste can alter the bacterial communities in urban soils, leading to simplification of their structure and dominance of forms that are resistant to various pollutants. This shift can result in the accumulation of potentially pathogenic bacteria such as *Escherichia*, *Enterobacter*, *Klebsiella*, and *Alcaligenes*, as well as allergenic bacteria from genera such as *Rhodococcus* and *Micrococcus*. This indicates a violation of

the ecological function of the soil as a “bacterial filter” and poses a threat to human health. Additionally, urban soils can exhibit characteristics similar to those found in southern regions, including a greater prevalence of the *Aspergillus* genus, which could pose a risk to individuals with weakened immune systems (Zvyagintsev, 1987).

The soils of urban areas differ from their natural counterparts in characteristic features, which generally include high bulk density and pollution, alkaline pH, as well as low nutrient content, with some with some exceptions, such as phosphorus and nitrogen content (Chen et al., 2014), grass cover density and plant litter thickness. However, the diversity, heterogeneity, and spatial variability of urban soils, as well as the level of anthropogenic impact, can make it difficult to clearly distinguish them from their natural counterparts in some parameters, particularly from a microbiological perspective (Table 1).

Pollution, land use change, soil compaction, and transformation of vegetation cover affect soil microbial properties, shaping microbial community of urban soils different from natural reference. They have direct and indirect impacts on the soil microbiome, such as altering the microbial community composition, reducing microbial diversity, and affecting microbial activity (Fig. 1). Given that microorganisms play a crucial role in providing a wide range of soil ecological functions and are highly sensitive to environmental conditions (Dobrovol'skaya et al., 2015; Korneykova and Nikitin, 2021), they can serve as effective and sensitive indicators of these functions (Schloter et al., 2018). For instance, studies of the soil microbial properties of forest parks have demonstrated changes in the microbial indicators of the soil carbon and nitrogen cycles under the influence of urbanization, particularly vegetation management practices (Ananyeva et al., 2023; Wang et al., 2023). These changes are expressed in a decrease in the microbial biomass carbon content, respiration activity, and the availability of soil carbon and nitrogen pools, which considered as the main indicators of soil quality (Schloter et al., 2003).

The sustainable development of urban green areas is dependent on the interaction between microbial and plant communities, their self-regulatory mechanisms, and their ability to adapt to climate change and anthropogenic stress (Barthel et al., 2019). Soil-plant systems in urban environments are highly sensitive to natural and anthropogenic stresses such as climate change, pollution, and soil salinization, which can lead to a reduction in the provision of ecosystem services and ultimately the appearance of disservices and degradation of the ecosystem (Liu et al., 2022).

Fig. 1 Main factors influencing the urban soil microbiome and potential consequences of this influence.

This chapter aims to assess the impact of various factors of urban environment on the state of the soil microbiome using the microbial biomass, microbial respiration, community level physiological profile, taxonomic structure as informative indicators which widely used in urban soil science studies (Fig. 2).

Specifically, we examine the effect of different management practices on the soil microbiome properties, including (i) typical management practices of lawns with different trees for the case of a university campus, (ii) artificial landscaping of a tremendous green roof for the case of Zaryadye Park; and (iii) soils of urban green infrastructures under severe climatic conditions for the case of Arctic cities. We assume that climate. Aboveground vegetation and management practices are key drivers affecting soil microbial community in urban environment.

Case studies of microbial activity, diversity, and functioning in urban soils

The effect of typology and composition of urban green infrastructures on soil microbiome for the case of university campus (RUDN University, Moscow)

The relationship between the aboveground plant and the soil microbial communities remain poorly understood in urban environment. The composition and diversity of soil microbial communities appear to be strongly influenced by the structure of the above-ground vegetation, including the ratio of coniferous and deciduous species, with a greater impact on the community structure (Urbanová et al., 2015; Chen et al., 2019; Rodríguez-Rodríguez et al., 2023). Trees could influence by directly and indirectly on physiological status of soil microbial community through litter quality and root exudation (Attiwill and Adams, 1993; Kiikkilä et al., 2006; Augusto et al., 2015). However, there is lack of data on the effects of vegetation type on microbial activity and functional diversity, particularly in urban ecosystems.

Fig. 2 The main microbial indicators and methods of their study.

The topsoil (0–10 cm) sampling campaign at RUDN University campus was organized in October 2019. Six tree species were selected: *Pinus sylvestris*, *Populus tremula*, *Acer platanoides*, *Tilia cordata*, *Picea abies*, *Betula pendula*. A composite soil sample was taken at a distance of 0.5 m from four opposite sides of the tree trunk from the top 0–10 cm layer at the beginning of October 2019 ($n = 5$ for each species, 30 in total) (Fig. 3). The following analysis were done in soil samples: pH_{water} (HANNA HI98129 pH meter, Romania), total carbon (C) and nitrogen (N) content (CHNS analyzer, Leco Corp., United States). Microbial biomass carbon (MBC) was measured by SIR method (Ananyeva et al., 2023). Basal respiration (BR) was measured as the rate of soil CO_2 release using gas chromatography (KrystaLLyuks-4000M; Meta-Chrom, Russia). The microbial metabolic quotient was calculated ($\text{BR}/\text{MBC} = q\text{CO}_2$). The capacity of the soil microbial community to metabolize diverse organic monomers (community-level physiological profiling, CLPP) was measured by the MicroResp™ technique for non-calcareous soils (Campbell et al., 2003). Microbial functional diversity was assessed through the Shannon-Wiener index: $H_{\text{CLPP}} = -\sum \text{Pi} \times \ln \text{Pi}$, where Pi is the ratio of respiration response to i substrate addition to total respiration response for all studied substrates. Samples for microbial properties measurements were taken from soils pre-incubated at 25 °C for 72 h (<https://estudogeral.uc.pt/bitstream/10316/24942/1/1-s2.0-S1470160X13003142-main.pdf>). Descriptive statistics were used to determine the mean, standard error, and variation coefficient. Significant differences in the variables between the studied tree species were examined by one-factor analysis of variance (ANOVA) with Tukey's multiple comparison test. Prior to the analysis, variance homogeneity was checked by Levene's test. The CLPP results were processed hierarchically using Ward's minimum variance method.

Among the studied chemical properties, only soil pH differed between lawns with different tree species (Table 2). Distribution of soil MBC and BR between studied groups didn't match (Fig. 4A and B). The lowest soil MBC content was under *Acer* tree (on average $538 \mu\text{g C g}^{-1}$), medium—for *Picea*, *Betula*, *Pinus* and (798, 805, 1124 $\mu\text{g C g}^{-1}$, respectively), and its highest content observed under *Populus* and *Tilia* (1378 and 1445 $\mu\text{g C g}^{-1}$). Soil BR didn't significantly differ between trees ($P = 0.1$). Specific respiration was higher for *Betula* and *Picea* by 1.3–2.1 times compared other species (Fig. 4C).

Considering the CLPP the studied samples were grouped in three clusters (Fig. 5A) (1) soil under *Tilia* tree with extremely high microbial response on diverse set of organic substrates (glucose, fructose, galactose, glycine, ascorbic and oxalic acids), (2) soil under *Acer* characterized by narrow spectra of organic substrates (ascorbic and oxalic acids) rapidly utilizing by microorganisms, (3) soil under *Betula*, *Picea*, *Pinus*, *Populus* with domination of microbial groups actively consumed two types of substrates—carbohydrates (fructose, glucose) and carboxylic acids (ascorbic and oxalic acids). The highest functional diversity of microbial community was found for *Betula*, but the lowest one for *Acer* (Fig. 5B). Hence, the metabolic status of soil microbial community and its capacity to decompose different organic compounds could be driven by the urban greening strategy. Besides, soil microbial community under *Betula* have high activity in utilizing phenolic acids by other words derivatives of aromatic hydrocarbons (organic pollutants). Perhaps, the high functional diversity of microbial community and capacity to utilize phenolic acids in soil under *Betula* could be explained by the relative lower its pH value (Table 2, Fig. 6). Interesting that soil MBC content and BR more related with N content than C ($r_s = 0.7$ vs. 0.6 and $r_s = 0.6$ vs. 0.5, respectively).

Fig. 3 The map of the soil sampling sites, RUDN University (55.652 N, 37.496 E, Moscow Russia).

Table 2 Topsoil properties (0–10 cm layer) for lawns with different tree species and diameter at breast height of trees (DBH).

Properties	Acer	Betula	Picea	Pinus	Populus	Tilia	P
pH	7.93 a(4)	6.48 c(7)	7.00 bc(12)	6.95 bc(10)	7.48 abc(1)	7.88 ab(4)	***
C, %	3.08/(20)	3.00/(23)	3.35/(34)	3.50/(10)	4.09/(29)	4.97/(54)	0.37
N, %	0.20/(33)	0.23/(19)	0.23/(22)	0.27/(11)	0.26/(22)	0.32/(43)	0.21
C:N	16.11/(21)	12.71/(8)	14.11/(19)	12.83/(9)	15.29/(13)	14.89/(15)	0.15
DBH	82.6/(8)	81.4/(10)	69.0/(13)	89.8/(20)	82.8/(7)	85.5/(8)	0.05

Values represent means with the variation coefficient (%) in brackets. Different letters indicate significant differences between groups (*** $P < .001$, ** $P < .01$, * $P < .05$, ANOVA with Tukey's multiple comparison test).

**Fig. 4** Mean plots with standard error of soil microbial biomass carbon (A), basal respiration (B), and microbial metabolic quotient (C) for lawns with different tree species. Different letters indicate significant differences between groups (ANOVA with Tukey's multiple comparison test, $P < .05$).**Fig. 5** Heatmap of CLPP represented by respiration response of microbial community on different organic substrates (A), mean plots with standard error of microbial functional diversity (B), contribution microbial groups utilized carbohydrates, amino-, carboxylic- and phenolic acids to CLPP (C) for lawns with different tree species.

Fig. 6 Relationships between microbial (MBC, BR, qCO_2 , respiration response on carbohydrates, amino acids, phenolic acids, carboxylic acids), chemical (pH, C, N, C:N) properties and tree diameter at breast height, DBH ($n = 30$). Correlation matrix shows Spearman's correlation coefficients in upper triangle and ellipse (red and blue—negative and positive relationship) in lower triangle.

Thus, belonging tree to certain group (coniferous or deciduous) didn't contribute to microbial properties of urban soils. Instead, individual tree species and soil conditions (pH, C, N contents) determined the microbial biomass, microbial functional diversity and CLPP. Consequently, the most favorable conditions for microbial community (high biomass and diversity) were found for urban soil under *Betula*, whereas *Acer* determined the least favorable conditions for soil microbiome.

From landscape variability to soil microbial diversity: A case study of a tremendous green roof in Zaryadye Park (Moscow, Russia)

In recent years, there has been a growing trend in urban areas to incorporate green spaces using soil construction based on soils and soil substrates characteristic of various zonal ecosystems relocated to the centers of megacities (Brenneisen, 2006; Francis and Lorimer, 2011).

An exceptional example is Zaryadye Park, which was established in Moscow in 2017. This space can be described as a tremendous green roof built over underground infrastructures (exhibition halls, parking and technical facilities) with extensive utility systems. Despite its relatively small area of 10.2 ha, Zaryadye Park successfully replicates vegetation zones from the European part of Russia, including tundra, coniferous and broad-leaved forests, birch forests, meadows, and subtropics. Maintaining the growth and development of vegetation in these diverse landscapes, within a uniform climatic environment and on artificially created topography and substrates in the heart of a bustling metropolis, presents a unique and challenging task. It requires optimal soil and ecological conditions, including a diverse and specific microbiota that supports the requirements of each simulated landscape.

Studies on the soil microbiota of green roofs are limited, with vegetation diversity mainly associated with a thin fertile layer, emphasizing the fundamental role of soil microorganisms in its formation and maintenance (Brenneisen, 2006). The resilient and diverse soil microbiome plays a crucial role in the functioning of green roofs, contributing to improved vegetation cover, drought tolerance, pathogen protection, increased nutrient availability, salt tolerance, productivity, and substrate stabilization (John et al., 2014; Molineux et al., 2014; Ondoño et al., 2014; Fulthorpe et al., 2018) (Fig. 7). However, it is known that anthropogenic factors can significantly influence the evolution of the soil microbiome, which may be particularly evident in artificially created plant communities, leading to the formation of unique microbial communities.

Based on the available data, the dynamics of microbial biodiversity in urban soil ecosystems exhibit a multidirectional pattern. There is a noticeable decrease in the diversity and abundance of microscopic fungi compared to natural ecosystems, while bacterial communities tend to become more diverse (Abrego et al., 2020; Tedersoo et al., 2020; Donald et al., 2021). This shift in microbial composition is accompanied by a redistribution of bacterial community taxa, with an increase in the representation of fast-growing r-strategists, including human and plant pathogens (Donald et al., 2021). At the same time, data on the functional diversity of the urban soil microbial community, which is an important indicator of its quality, are limited, and its assessment is of particular interest.

Fig. 7 The role of the soil microbiome in the formation and maintenance of green roofs (Fulthorpe et al., 2018). Zaryadye Park is an example of intensive green roof technology.

Soil survey in Zaryadye park, was carried out in summer 2022. Soil samples were collected from 0 to 10 cm in artificial green roofs with different vegetation types presented by zones: mountain tundra (MT), humid tundra (HT), pine forest (PF), spruce forest (SF), mixed forest (MF), birch forest (BF), steppe (S), floodplain (F), meadow (M), subtropical forest (SPF) and urban greening (UG). Disturbed and undisturbed areas were visually identified in each landscape type. A total of 22 zones were examined. CLPP and microbial functional diversity assessed using the methods described earlier in section “The effect of typology and composition of urban green infrastructures on soil microbiome for the case of university campus (RUDN University, Moscow)”.

The microbial communities of dissimilar natural zones demonstrated the highest physiological activity, manifested on a wider range of substrates: tundra, steppe, urban green areas, and the glass bark zone, in which plants of the subtropical zone are represented (Fig. 8A). The highest activity was observed in the tundra, which represents a landscape zone that is particularly challenging to replicate in Moscow due to its markedly different natural conditions. The revealed diversity of physiological groups of soil microorganisms indicates the existing potential of the microbial community for destructive activity not only in relation to readily available carbohydrates, but also in relation to substrates of amino acid groups, carboxylic and phenolic acids (Fig. 8B). Maximum functional diversity was also observed in undisturbed areas within the steppe landscape zone, as indicated by the Shannon index ($H = 2.47$) (Fig. 8C).

An analysis of the state of the park soils and their comparison with the parameters laid down at the opening of the park made it possible to conclude that the functional diversity depends on the content of organic matter. The tundra area, characterized by significantly higher levels of organic matter compared to the minimum acceptable values, displayed the most pronounced response to the introduction of various substrates (Fig. 9). The combined zones forming a single cluster represented less disturbed areas, further highlighting the impact of anthropogenic pressure intensity on the physiological activity of the microbial community.

Fig. 8 Heatmap of CLPP represented by respiration response of microbial community on different organic substrates (A), microbial functional diversity (B), contribution microbial groups utilized carbohydrates, amino-, carboxylic- and phenolic acids to CLPP (C) for disturbed and non-disturbed areas of the landscape zones of Zaryadye Park. MT - alpine tundra; HT - humid tundra; PF - pine forest; SF - spruce forest; MF - mixed forest; BF - birch forest; S - steppe; F - floodplain; M - meadow; SPF - subtropical forest; UG - urban greening; d - disturbed area.

The microbial community of the park has patterns inherent in sustainable urban communities: reduction in species diversity and simplification of the structure of microscopic fungi, reduction in the number of cellulolytic fungi species, and redistribution of taxa towards potentially pathogenic species (Marfenina et al., 2011; Abrego et al., 2020). At the same time, the low share of actinomycetes, identified in the soil, on the contrary, indicates the initial stage of succession (Zviagintsev and Zenova, 2001).

These contradictions testify to the formation of unique communities of soil microorganisms in the park in which microbial successions can deviate classical assumptions. Perhaps, the territory of the park can be considered in the context of combining many ecotones-transitional environments between different plant communities (landscapes of the park), which enhances its role in the formation and conservation of biodiversity.

Arctic urban soil microbiome (Apatity, Russia)

The environmental consequences of urbanization are especially noticeable and challenging to evaluate in Arctic cities, where the restoration and development of ecosystems are constrained by climatic factors such as low temperatures and soil conditions such as nutrient deficiency (Goryachkin et al., 1999; Grosse et al., 2011).

The presence of organic substrates used in soil constructions in urban areas, combined with the warmer climate characteristic of “heat island” (urban area with significantly higher temperatures than surrounding rural areas), creates new ecological niches that facilitate the growth and development of soil microbial communities. For example, in the topsoil horizon of urban soils of Murmansk and Apatity, the microbial biomass and the number of copies of the rRNA genes of archaea, bacteria, and fungi were lower than in natural soils and amounted to (10^6 – 10^{10} , 10^9 – 10^{10} , and 10^7 – 10^9 , respectively). However, the opposite was shown for the subsoil horizons, where the neutral reaction, high carbon and nutrient content, and low pollution created favorable conditions for microbial development (Fig. 10). Similarly, total microbial biomass in urban soils (0.55–0.75 mg/g) was lower compared to 1.02 mg/g in background soil, while microbial biomass in urban subsoils was 2–2.5 times higher than in natural conditions. In addition, significant morphological changes were noted in microscopic fungi, with small spores predominating in urban soils, and mycelium predominating in forest soils. An increase in the diversity of microscopic fungi was also noted.

Fig. 9 Comparison of the content of organic matter in different landscapes. The red line represents the minimum permissible level of organic matter content in the soils during the creation of most landscapes. T – tundra; STF – subtropical forest; F – floodplain; SF – spruce forest; S – steppe; BF – birch forest; M – meadow; MF – mixed forest; SPF – subtropical forest; UG – urban greening.

Fig. 10 Profile distribution of the total microbial biomass (A) and fungi: prokaryotes portion (B). MUR-U1, MUR-U2 – urban soil; MUR-NR – forest soil.

Arctic cities experience a strong anthropogenic load from industrial enterprises, the emissions of which have a strong negative impact on the state of terrestrial ecosystems. One of the brightest examples of such a city is Norilsk (Taimyr Peninsula), Monchegorsk (Kola Peninsula), etc. In the soils of such cities, microbiological activity is very suppressed. Among the cultivated bacteria, oligotrophs, adapted to existence in nutrient-poor soils, predominate. In general, soils are characterized by low numbers of microorganisms, biomass, and enzymatic activity compared to other northern regions that do not experience a strong anthropogenic load from industrial enterprises. However, compared with the background soils of the study area, in urban areas there was a slight increase in the biomass and diversity of soil bacteria and microscopic fungi, but at the same time, the proportion of opportunistic microfungi and bacteria of the *Escherichia coli* group, which can pose a danger to human health, increases.

In the soils of such cities, as a rule, there is a restructuring of the functional and species structure of the microbial community in comparison with the natural soils. For example, in different regions of Norilsk, soils were dominated by microorganisms capable of decomposing a group of amino acids and carbohydrates, while carboxylic acids dominated in natural soils. Among microfungi, melanin-containing species, which are known for their increased resistance to extreme conditions, were predominant.

When establishing Technosols, various types of organic materials in different ratios are commonly considered, primarily due to their availability (Ivashchenko et al., 2021). In the case of Apatity, peat, which is widely available, and mining wastes, which are industrial by-products, are frequently used as components in soil construction (Kremenetskaya et al., 2019).

During the monitoring of microbiological properties of Technosols of urban laws in Apatity for 26 months, the following trends were observed (Fig. 11).

For the microbial biomass carbon, there was an increase in all studies values (Table 3). Microbial activity increased during the first year of functioning, then there was a decrease and, accordingly, a return to the initial state. Specific respiration, which

Fig. 11 Trend of microbial carbon indicators of Technosols of urban lawns in Apatity.

Months	C_{mic}	BR	qCO_2
2	1.7	1.6	1.0
14	1.8	1.9	0.7
20	1.6	1.0	0.6
26	2.6	1.6	0.6
Result	Increased	Return to initial state	Decreased

characterizes the ecophysiological state of soil constructions, decreased over time, especially actively during the first year of functioning (2–14 months).

At the beginning of the functioning of the soil constructions, there was a significant variation in the observed values (Fig. 12). One year later, it decreased for microbial biomass carbon and specific respiration, and became strong for basal respiration. By the end of the observations for all parameters under examination, the variation was minor, which can probably be characterized as a more stable condition.

To characterize the state of the soil constructions, the indicators were compared with the values obtained from the analysis of the background soils, the state of which was the reference of sustainable functioning (Table 4).

For all parameters, a significant approximation to the background values was noted, and for the microbial metabolic quotient, the background values were reached, indicating the attainment of an equilibrium state.

In the functional structure of the microbial community in the soil structures of Apatity lawn, an increase in the consumption of substrates belonging to the carbohydrate group and a decrease in the consumption of carboxylic acids, which are the easiest and most accessible substrates for utilization, were observed (Fig. 13). Furthermore, there was an increase in the uptake of the more difficult-to-degrade phenolic acids.

Months	C_{mic}	BR	qCO_2

Arctic cities experience a strong anthropogenic load from industrial enterprises, which emit pollutants that strongly impact terrestrial ecosystems. Norilsk (Taimyr Peninsula) and Monchegorsk (Kola Peninsula) serve as prominent examples. In the soils of these cities, microbiological activity is heavily suppressed. Cultivated bacteria primarily consist of oligotrophs, specially adapted to survive in nutrient-depleted soils. In general, these soils exhibit lower microorganism counts, biomass, and enzymatic activity compared to other northern regions unaffected by intense industrial activities. However, when compared to the background soils in the study area, urban regions display a slight increase in both soil bacteria and microscopic fungi biomass and diversity. Nevertheless, this increase is accompanied by a higher proportion of opportunistic microfungi and bacteria from the *E. coli* group, which can pose risks to human health.

In the soils of such cities, as a rule, there is a restructuring of the functional and species structure of the microbial community in comparison with the natural soils. For example, in different regions of Norilsk, soils were dominated by microorganisms capable of decomposing a group of amino acids and carbohydrates, while carboxylic acids dominated in natural soils. Among microfungi, melanin-containing species, which are known for their increased resistance to extreme conditions, were predominant.

Urban green infrastructure can become a hotbed of microbial growth and soil diversity in a city from a polar region. This result should not be directly interpreted as a positive impact of urbanization on the soil microbiome, since the taxonomic and functional composition of microbial communities in urban soils can be very diverse. At the same time, urban soil is as a potential ecological niche for the development of the soil microbiome and a source of important ecosystem services, such as nutrient cycling and biodiversity control. The importance of ecosystem services and the harmful services provided by the urban microbiome will further increase after global warming scenarios and should be considered in sustainable soil management in Arctic cities.

Conclusion

In the urban context, the soil microbiome experiences a range of anthropogenic pressures, including contamination, land-use changes, and alterations in nutrient inputs. These factors impact the composition, diversity, and functioning of the soil microbiome. However, the extent and nature of these effects can vary greatly across different urban regions due to variations in urbanization patterns, local pollution sources, and management practices. For the development of a sustainable ecosystem in urban green areas, it is crucial for the microbiome to create conditions in terms of quantity, quality, and functionality.

The recognition of the importance of studying the soil microbiome has spurred significant advancements in methods for analyzing the microbiological properties of soil. Despite the active development of methods for analyzing the soil microbiome in the city, there are still no standards for soil microbiological properties, except those developed for human pathogens. The development of such standards must take into account the specifics of the region under study, including both natural and anthropogenic factors and is complicated by the variability of the results obtained and their non-obvious interpretation.

Currently, the assessment of urban soil is given by comparing its characteristics with nearby natural counterparts, using the main microbial indicators. These indicators provide valuable information on taxonomic diversity, community structure, microbial activity, and functional potential, enabling the characterization of ecosystem provisioning functions. However, the question remains open regarding the selection of the most informative indicators for assessing urban soil microbiomes.

Moreover, it is essential to advance our understanding of the relationships between microbial indicators and ecosystem functioning in urban soils. This includes investigating the contributions of urban soil microorganisms to vital processes such as nutrient cycling, organic matter decomposition, pollutant degradation, and plant-microbe interactions. By examining these relationships, we will be able to effectively evaluate the influence of the soil microbiome on the sustainability, resilience, and overall functionality of urban ecosystems.

Abstract

In soil, microbial community structure is greatly influenced by physical and chemical components, especially nutrients and toxic ions. When located at either ends of the physicochemical range of properties, soils are called “extreme” and tend to be oligotrophic environments or characterized by strong nutrient imbalances. Their colonization depends on the interplay between the spatial and temporal structure of environmental restrictiveness and the microbial adaptive potential, presence of biological networks and microbe movement to new habitats. Colonization is multiphasic and carried out by soil generalists, by endemic specialists, and by survivalists. Microorganisms inhabiting polar regions are critically involved in regulating Earth’s climate and carbon balance.

Key points

- The ability of microorganisms to thrive in inhospitable environments leads us to expand the boundaries of life and enter uncharted territory, where life itself may appear strange and foreign.
- Dispersal makes microbes ubiquitous, but selection by general and extreme soil characteristics decides their fate through strategies for survival that range from active growth to death.
- To overcome environmental stress, microorganisms can adopt strategies of compensation, conservation, protection, damage repair, and stress mitigation.
- Mechanisms for survival include development of DNA with high preponderance of specific base pairings, enhanced thermal stability and efficient repair mechanisms, a high level of crucial gene redundancy and genome plasticity with up-regulation of environmentally relevant genes, proteins with modified flexibility, changes in membrane composition, including amount and type of lipids, and regulation of fluidity.
- Knowledge of the microbiology of extreme soil environments has resulted in a vast field of practical applications, such as solvent and polymer production, agricultural enhancements, pollutant removal, and clean energy production.
- Microorganisms that inhabit polar regions are critically involved in regulating the Earth’s climate and carbon balance.

Introduction

Soils of the Earth represent a diverse set of heterogeneous and discontinuous ecosystems, fragmented into an incommensurate number of microhabitats, both discrete and variably interconnected. In these systems, self-organization (Young and Crawford, 2004) occurs at different scales, from the nanometer to the kilometer range, in a fractal mode sustained by biological, physical, and chemical interfacial processes. Depending of their location at any particular moment, 10^{30} bacterial and archaeal cells, which themselves can be grouped into more than 10^{12} species (Locey and Lennon, 2016), can be introduced into soil with a varying level of probability about their future. There, their fate, characterized as either growth, survival in the dormant state or death, will be determined by the interplay between their own physiology, morphology and genetics and the self-organizational processes occurring in that soil.

The impact of soil heterogeneity on diversity of colonizing microbial communities has been studied through a variety of approaches, one of these being to examine the microbiology of soils located at the extremes of the physicochemical range of soil properties. Such soils are called “extreme soils”. A microorganism introduced in an extreme soil will be subjected to the stressful conditions normally occurring in soil, and to an additional, intense, constant, and intrinsic selection pressure. This additional selection pressure arises because an extreme soil harbors one or several defining characters that superimpose a supplementary chemical or physical challenge to common obstacles faced by soil microbial colonizers. The microbial colonization patterns of extreme soils are defined by the interplay between the spatial and temporal structure of environmental restrictiveness with the: (i) microbial adaptive potential; (ii) biological networks; and (iii) dispersal, defined here as movement of microbes leading to their introduction in a new soil habitat (Fig. 1).

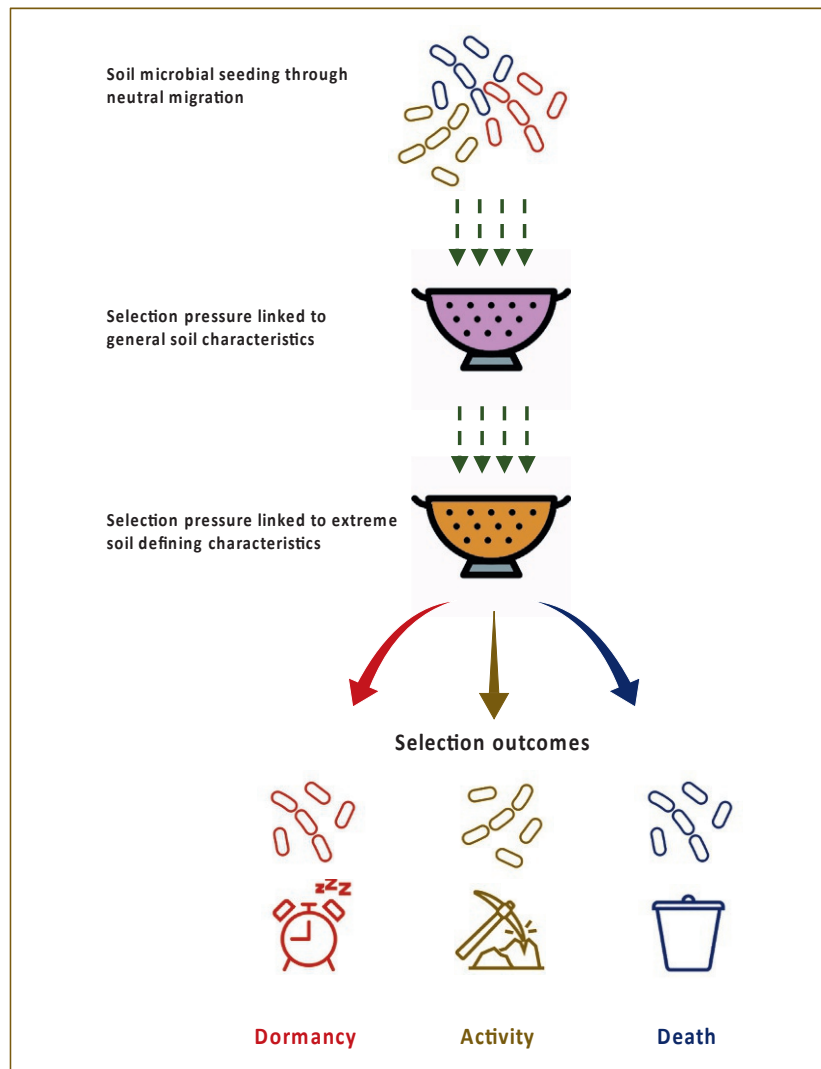

Fig. 1 Dispersal makes microbes ubiquitous, but selection by general and extreme soil characteristics decides their fate.

Extreme soils and extreme microbes

Soil microbial community structure is markedly influenced by soil organic carbon content and pH, together with other factors such as temperature, sand proportion, water content, electrical conductivity, as well as the phosphorus, sulfur, calcium, magnesium, iron, and aluminium content. These physicochemical properties vary widely, at scales ranging from the micrometer up to continental dimensions (Tecon and Or, 2017). In extreme soils, one or several soil environmental restrictions are pushed to an extreme value, defining the soil itself and the microbial community that inhabits it. All active members of an extreme soil community demonstrate genetic, physiological, and morphological adaptation to this defining character, in the form of resistance or tolerance. Other soil properties contribute to structure the microbial community, since adaptation to the defining character is not sufficient, by itself, to confer on a microorganism the capacity to inhabit a particular extreme soil, either as a dormant organism or else as active cells (Vera-Gargallo et al., 2019).

Extreme soils belong to a variety of Reference soil groups as defined by the World Reference Base, and it is not possible to establish an unequivocal and complete correlation between certain soil groups and the extreme character. Rather, those soils are typified as possessing one defining character or a set of defining characteristics, which are identified, not only by their intensity, but also by the fact that they are constantly expressed, or at least are maintained over extended time periods (Table 1).

Microbial adaptive potential to extreme soils

All soils are extreme, but some soils are more extreme than others

Harsh conditions, including low nutrient status, fluctuating water availability, occurrence of phenolics or other toxic compounds, as well as intra and interspecific competition, generally prevail in soils (Barberán et al., 2014). As decades of attempts at reliably introducing microbial inoculants in soil have shown, efficient microbial colonization of soil requires specific adaptive traits that are narrowly distributed. Colonization is a multiphasic phenomenon, carried out by soil generalists occurring in large numbers at a variety of sites and in different soil types, by specialists with a high degree of endemism, and by survivalists such as *Escherichia coli* (Moynihan et al., 2015; Van Elsas et al., 2011), capable of maintaining populations in soils for extended time periods following their transport from a different, preferential, habitat. Survival may be achieved through dormancy, characterized by a combination of reduced or abolished metabolism and maintenance of cellular integrity. The ultimate option open to soil microbes is death, whereby cell content is made available to other organisms. These descriptions of microbial strategies do not represent discrete categories, but rather compose a fluctuating continuum of adaptation levels. Microorganisms transition along this continuum because of spatial and nutritional heterogeneity (Joergensen and Wichern, 2018; Lennon and Jones, 2011), of soil community composition (Moynihan et al., 2015), and thanks to genomic evolution (Jang et al., 2017). Members of the microbial community locate themselves along this continuum, with the sum of microbial positions defining an overall community balance along a stress scale defining death, dormancy and growth strategies (Fierer, 2017). Extreme soil defining characters tip the overall community balance against growth and competition strategies, and in favor of stress tolerance (Fig. 2).

Successful soil microbes are found at both numerous and environmentally diverse sites. Efficient microbial soil colonizers share traits related to genome structure and functional potential. For example, bacteria with larger genomes and more metabolic and functional capabilities are also more successful at soil colonization (Barberán et al., 2014). On top of the regular traits common to all efficient soil colonizers, microbial activity in extreme soils is contingent on adaptation to a set of defining characteristics and on expression of specialized physiological responses (see Table 1 above). Thus, to the defining characteristics of extreme soils correspond equally defining properties of active microbial colonizers. Whereas extremophily is often associated with archaea, one lesson that can be extracted from the study of extreme soil microbiology is that extreme soils harbor microbial communities akin to those of normal soils, in terms of the general representation of the three domains of life. Archaea, bacteria, and eukaryotic microbes coexist in extreme soils as they do in normal soils. In particular, fungi, either unicellular or in filamentous form, and lichenized or non-lichenized, occur abundantly in all types of extreme soils and it has been suggested that they may be more resistant than bacteria under certain conditions prevalent in these environments (Dragone et al., 2020).

Being constantly present, extreme soil defining characteristics determine a corresponding stability in the colonizing microbial communities. Shaped by a constant historical environment, soil microbial assemblages become sensitive to change, leading to poorer functional acclimatization capacity as compared to communities inhabiting more fluctuating environments (Bardgett and Caruso, 2020). Microbial transformations in extreme soils result from activities of narrowly adapted specialists, existing in environments of low carrying capacity. When changes in the intensity of extreme soil defining characteristics occur, extremophile microbial communities express some level of resistance, resilience and functional redundancy, as do other communities from normal soils (Allison and Martiny, 2008). However, defining characteristics of extreme soils directly alter microbial survival and thus exert a strong negative impact on diversity or abundance of soil biology. Because functional redundancy may be low in extreme soil environments, and because of the rarity of changes (see above), microbial communities colonizing extreme soils may be more fragile and less resilient than communities found in other soils.

Microbial adaptation mechanisms in extreme soils

Agriculture, forestry and recreational activities showcase soils as life-sustaining devices (FAO and ITPS, 2015). Indeed, even the most barren soils generally harbor microbial life. Although no signs of life were detected in a particular region of Antarctica, facing a

Table 1 Extreme soils and their defining characteristics.

Extreme soil type	Defining characteristic	Other bio-limiting characteristics	Examples of microorganisms active in extreme soil			Characters of microorganisms	References ^a
			Bacteria	Archaea	Eukaryotes		
Defining character driven by climate							
Cold soils	Presence of permafrost below an active soil layer	Freeze-thaw cycles, desiccation, starvation, radiation, UV exposure	Psychrophilic and psychrotrophic bacteria; anaerobic bacteria: sulfate reducers, Fe(III) reducers and denitrifiers; methanotrophs	Acetoclastic and hydrogenotrophic methanogens	Fungi, including yeasts	Optimal growth temperature around 15 °C (growth down to –15 °C)	De Maayer et al. (2014) and Jansson and Tås (2014)
Hot arid soils	Ratio of precipitation to potential evapotranspiration of 0.05–0.2 for arid soils and of less than 0.05 for hyperarid soils	Extreme fluctuations in temperature, low nutrient status, high levels of ultraviolet radiation, strong winds	Communities dependent on microbial primary producers, such as cyanobacteria; Bacteroidetes and halophilic bacteria; aerobic heterotrophs from the Terrabacteria superphylum, including Actinobacteria and Chloroflexi; trace gas oxidizers	<i>Halobacteriaceae</i>	Green algae; melanin-containing fungi	Biological soil crust formation; hypolithic or endolithic colonization; presence of lichens	Bay et al. (2018), Jung et al. (2020) and Makhalanyane et al. (2015)
Defining character driven by soil chemistry and water content							
Hypersaline soils	Electrical conductivity of a saturated soil extract >15 dS m ^{–1}	Temperature, pH, nutrient availability, solar radiation	Moderate and extreme halophiles: Bacteroidetes, <i>Salinibacter</i> Balneolaeota, Rhodothermaeota; cyanobacteria of the <i>Halothece</i> cluster	Halophilic archaea: <i>Natronomonas</i> , <i>Halococcus</i> , <i>Halobacterium</i>	Black yeasts, e.g., <i>Hortaea werneckii</i> , filamentous fungi, e.g., <i>Cladosporium herbarum</i> ; <i>Chlorophyceae</i> , e.g., <i>Dunaliella</i>	Growth of halophiles at 2–5 M NaCl; water potential –1.5 to –40 Mpa; colonization of rock habitats in hypersaline arid soils	Crits-Christoph et al. (2016), Musa et al. (2018) and Vera-Gargallo et al. (2019)
Peatland soils	Flooded ecosystem where the production rate of biomass exceeds its decomposition rate	Anaerobiosis in deeper horizons; high acidity	Vertically stratified bacterial community; Bacteria, including methanotrophs of the Proteobacteria and Verrucomicrobia phyla; N-fixing <i>Burkholderia</i>	Archaea, including methanogens in the deep waterlogged horizon, or catotelm	Fungi, especially in the upper layer, or acrotelm: saprophytes, including polyphenol-degraders; mycorrhizal symbionts; green algae	Species-specific association between yeast and <i>Sphagnum</i> plants; unique acidophilic methanotrophs	Andersen et al. (2013)
Defining character driven by soil physics							
Deep subsurface	Environment characterized by darkness and anaerobiosis, where temperature and pressure increase with depth	Scarce water and organic matter, substrates limited to dissolved minerals; colonization dependent on fractures or porosity in rocks	Microbial hydrogen generation though fermentation, nitrogen fixation and other reactions; hydrogen consumption through acetogenesis, sulfur and iron reduction and other reactions; hydrogen-utilizing cyanobacteria as primary producers; Alphaproteo-bacteria, Bacteroidetes	Hydrogen consumption through methanogenesis	Ascomycota	Anaerobic oxidation of hydrogen using extracellular electron acceptors such as iron and manganese oxides, or phenolic compounds	Escudero et al. (2018) and Gregory et al. (2019)

Fig. 2 Simplified view of soil microbiota, and of their growth and survival strategies. Strategies are arranged along a continuum (double-headed lines on top of the Figure going from near death dormancy to active growth). Soil microbiota, illustrated as a bar placed in equilibrium, are comprised of components performing activities or harboring properties related either to stress tolerance, or else to competition. (A) In normal soils, a fluctuating equilibrium exists between stress tolerance and competition. Properties attributed to each of these two microbial strategies are indicated below the bar representing the soil microbiota. (B) Extreme soil defining characters tip the balance in favor of stress tolerance. This results in loss of diversity, decrease in competition-related activities, increased dependence on microbial-driven nutrient cycling, and expression of various other community properties as indicated.

unique combination of cold temperatures, low water potentials, and high salt concentrations (Dragone et al., 2020), microorganisms have devised means to cope with most extreme soil defining conditions or sets of defining conditions.

Microorganisms resort to five possible strategies to overcome environmental stress: compensation, conservation, protection, damage repair, and stress mitigation.

(i) During the *compensatory response*, microorganisms seek to restore equilibrium and to maintain normal functions. For example, some halophiles adopt the “salt-in” strategy, where osmotic balance is achieved by accumulating high intracellular concentrations of inorganic salts, such as KCl (Gunde-Cimerman et al., 2018). (ii) When resorting to the *conservation response*, microorganisms enter dormancy. Whereas endospore formation represents a form of absolute dormancy, other forms are also possible, including differentiated resting structures such as arthrospores, conidia, cysts or akinetes. Many organisms can enter physiological dormancy without obvious morphological differentiation; this is a very common response, since 90% of soil microorganisms are dormant (Lennon and Jones, 2011). (iii) *Protective responses* are used to maintain the physical integrity of living organisms. Desiccation may cause water loss resulting in cell-volume collapse and in serious damage to cellular macromolecules such as proteins and nucleic acids. To protect themselves against desiccation, many bacterial cells accumulate compatible solutes, including carbohydrates, amino acids, quaternary amines, and tetrahydropyrimidines. (iv) Capacity for *damage repair* is exemplified by *Deinococcaceae*, which show an ability to withstand the lethal effects of DNA-damaging agents and to repair hundreds of DNA double and single-strand breaks as well as other types of DNA damages following desiccation or gamma irradiation (Heulin et al., 2017). (v) The *mitigation response* occurs when microorganisms avoid excessive stress exposure by choosing favorable niches within their heterogeneous environment, where they encounter conditions favorable to survival and growth.

Irrespective of their capacity to express one or several of these strategies, extremophiles and non-extremophiles co-exist in all types of soils. Thermophiles are ubiquitous in soils, since upper soil layers provide temporal niches for their activity (Santana and Gonzalez, 2015). Various examples also exist of moderate halophiles being isolated from non-saline soils (Wu et al., 2020). Whether they remain active or dormant in these temperate habitats, these resistant or tolerant organisms constitute a ‘microbial seed bank’ from which extreme soil communities will be structured upon development of an extreme character. Conversely, the observation of recovery of microbial communities to their original state following cooling of coal fire-heated soils (Lee et al.,

Fig. 3 Stochastic resuscitation model for extreme soil colonization. The diagram is constructed in a manner analogous to the adaptive landscape architecture, with activity levels being depicted in lieu of fitness levels as is usual in adaptive landscape representations. Through aeolian or other modes of dispersal as proposed by Bass Becking, phylotypes A and B are introduced as dormant populations in a newly formed extreme soil environment. The stochastic model states that either phylotype A or phylotype B will be resuscitated first in any given microenvironment, with this faster phylotype stably occupying the niche characterized by extreme physicochemical conditions and low carrying capacity.

2017) suggests that non extremophile microbes are constantly reintroduced in some extreme soils from neighboring locations. They may then encounter death, inactivation, or dormancy in their new extreme habitat, or else perform successful adaptation.

The combination of the lethal or inactivating potential of extreme soil defining characters and of the existence in soils of microbial seed banks comprised of dormant microbes awaiting resuscitation may be at the origin of a stochastic founding effect (Lee et al., 2017), responsible for the large beta- and gamma-diversity observed between different extreme soils sharing the same defining character. According to this hypothesis, extreme soil community structure would be largely determined by the kinetics of resuscitation among extremophiles comprising the microbial seed banks. Those microorganisms that are reactivated first in a newly formed extreme soil become firmly and stably established in this environment, where a lack of antagonisms and signaling activity leads to long-term or quasi-permanent colonization patterns. Fig. 3 provides a graphic depiction of the stochastic founding effect prevalent in newly formed extreme soil environments. This view is inspired by adaptive landscape representations (Cavrilets, 2008), with phylotype activity replacing genotype fitness as the varying property of microbial communities.

In addition to the wide variation of community structure of extreme soils sharing similar properties, this stochastic founding effect of newly formed extreme soils would allow microorganisms capable of deep dormancy, such as the spore-forming *Bacillaceae*, *Chloroflexi* and *Dormibacteraeota*, to occur frequently in various types of extreme soils, where they can perform physiological adaptation. Other microorganisms harboring a resting stage, such as *Actinobacteria* and *Cyanobacteria*, are also frequent extreme soil colonizers. Table 2 presents examples of adaptation mechanisms displayed by microbial colonizers of extreme soils.

The same survival strategy may be adopted as a microbial response that would be common to a range of environmental challenges. Table 3 provides examples of multipurpose stress resistance strategies, each of which is adopted by extremophiles in a variety of contexts. In a modular assembly process, multipurpose strategies are associated in environmentally-specified combinations, to constitute the integrated physiological, ecological, and genetic tolerance identity of individual organisms.

Carbon and nitrogen metabolism in extreme soils

Because of the essentially total absence of plants or large animals, most extreme soils are oligotrophic environments, or at least are characterized by strong nutrient imbalances. Carbon and nitrogen are supplied by microbial primary producers, or else come from scant and inanimate external sources (Table 4). One consequence of this, apart from low cell numbers and prevalence of dormancy, may well be the slow pace of microbial community succession (Knelman et al., 2014). Thus, initial community assembly, determined by random microbial dispersal (Herbold et al., 2014) and the stochastic founding effect presented above, would result in non-convergent community compositions over relatively short geographic ranges, with a high degree of phylotype endemism. This pattern would be particularly striking in the case of fragmented habitats, such as rocks supporting *endo*- or *hypolith*ic colonization in hot (Chan et al., 2012) or cold (Cowan et al., 2014) deserts, or else ice-wedge polygons that are geometric formations comprised of a combination of ice, bog and water body (van Dorst et al., 2017).

In normal soils, atmospheric H_2 and CO oxidizers are members of the rare biosphere, each comprising about 1% of the total bacterial community. However, in various extreme environments, such as Antarctic deserts (Bay et al., 2021) and deep subsurface environments (Gregory et al., 2019), trace gas oxidizers are the main primary producers in soils with otherwise low photosynthetic input (see also below).

Table 2 Examples of adaptation mechanisms expressed by microbial colonizers of extreme soils.

Type of extreme soil	Category of adaptation			References
	Environmental	Molecular	Physiological	
Cold soils	Colonization of protected niches or “refugia”, as occurs for hypolithic communities; dormancy	Genome: high G + C content of DNA; high level of crucial gene redundancy; high genome plasticity. Proteins: increased flexibility; increased enzymatic activity; decreased thermostability. Up-regulation of genes encoding cold-shock proteins	Increased membrane fluidity; optimized membrane function; accumulation of cryoprotectants, and of antifreeze and ice nucleation proteins; accumulation of trehalose	De Maayer et al. (2014)
Saline soils	Endolithic and hypolithic colonization by cyanobacteria and other microorganisms provides access to water through various mechanisms, including halite deliquescence and extraction of crystallization water from gypsum rock	Highly acidic proteome; changes in membrane composition and regulation of fluidity	Two alternative strategies: “salt-in strategy” with the intracellular accumulation of high concentrations of inorganic salts, mainly KCl; “compatible solute strategy”, or accumulation of organic compounds compatible with cell processes (glycerol often found in eukaryotes, glycine betaine in prokaryotes)	Crits-Christoph et al. (2016), Gunde-Cimerman et al. (2018) and Huang et al. (2020)
Hot soils	Fungal thermophily is an adaptation to transient seasonal and diurnal high temperatures; high soil surface and phyllosphere temperatures contribute to presence of thermophiles in cool soils	Proteins with increased ion-pair content and disulfide bonds, forming high-order oligomers and with decreased flexibility at room temperature. Adjustment in membrane composition, including amount and type of lipids (including ether-linked lipids). Enhanced thermal stability of DNA due to DNA-binding proteins and association with monovalent and divalent salts. High G + C content of ribosomal and transfer RNAs and presence of modified nucleosides	Presence of adaptive base excision DNA-repair system; high ploidy level; fast RNA turnover; ability to cope with thermolabile metabolites by metabolic channeling or other mechanisms; accumulation of compatible solutes	Gerday and Glansdorff (2007), Godon et al. (2020), Powell et al. (2012), Rothschild and Mancinelli (2001) and Santana and Gonzalez (2015)
Arid soils	For cyanobacteria, localization at the soil surface or below the surface depending on humidity levels; formation of biological soil crusts	Enhanced capacity for DNA repair in <i>Deinococcus</i>	Accumulation of compatible solutes as osmoprotectants; synthesis of extracellular polymers; cell differentiation into resting stages (endospores, akinetes)	Ferrenberg et al. (2017) and Heulin et al. (2017)
Radioactive soils	Protection against ionizing radiation is a consequence of adaptation to desiccation and other stresses	Efficient DNA repair mechanisms (repair of single-strand and double-strand breaks, and of base modification)	Protection against oxidative injury, notably by maintaining a high intracellular Mn/Fe ratio	Pavlopoulou et al. (2016)

Biological networks and dispersal: Examples of extreme soils

Cold soils

Presentation of cold soils and of their microbial communities

Permafrost is defined as ground, comprised of soil, sediment, or rock, with inclusion of ice and organic material, that remains at or below 0 °C for at least two consecutive years. During the short arctic summer, the surface zone of permafrost sediments thaws, giving rise to the active layer. Active layer depths range from a few cm in the high Arctic to more than 2 m in subarctic regions. Permafrost can be cemented by ice, as occurs in the Arctic, or it may be dry, as in the Antarctic polar deserts or rocky areas where interstitial water is lacking (Wagner, 2008).

Table 3 Examples of multipurpose physiological, ecological, and genetic strategies in extremophiles.

Type of multipurpose strategy	Strategy provides resistance to:	References
Endolithic colonization	Desiccation under hot or cold conditions	Cary et al. (2010) and Wierzbos et al. (2018)
Dormancy	General stress	Lennon and Jones (2011)
Accumulation of compatible solutes	Salinity, desiccation, heat ^a	Empadinhas and da Costa (2008), Santos et al. (2007) and Schmid et al. (2020)
DNA repair mechanisms	Desiccation, heat, ionizing radiation ^b	Pavlopoulou et al. (2016) and Ranawat and Rawat (2017)
Melanin and mycosporine-like amino acid production by fungi, cyanobacteria, and other microorganisms	Excessive heat or cold, extreme pH or osmotic conditions, UV and ionizing radiations	Gessler et al. (2014) and Gostinčar et al. (2015)

^aSome compatible solutes are restricted to hyperthermophiles; in some organisms, heat resistance is associated with radiation resistance.

^bIonizing radiation resistance is believed to arise as a by-product of desiccation and heat resistance involving DNA repair mechanisms and protection against reactive oxygen species.

Table 4 Metabolism of carbon and nitrogen in some examples of extreme soils.

Type of extreme soil	Metabolism of		References
	Carbon	Nitrogen	
Cold soils (permafrost layer)	Utilization of plant and animal residues accumulated over thousands of years	Nitrogen fixation with organic carbon as energy source	Mackelprang et al. (2011)
Cold soils (active layer)	Methanogenesis at sub-zero temperatures Degradation of organic carbon diffusing from permafrost, with production of carbon dioxide and methane Methanotrophy in the presence of oxygen	Assimilatory nitrate reduction Dissimilatory nitrate reduction, with production of molecular nitrogen and nitrous oxide intermediate	Mackelprang et al. (2011)
Cold desert soils (Antarctic soils)	Autotrophic carbon fixation; scavenging of H ₂ and CO from the atmosphere for use as energy sources	Functional capacity for nitrogen fixation in hypolithic communities	Cowan et al. (2014) and Ji et al. (2017)
Arid soils (halite endolith in the Atacama Desert)	Primary organic carbon production by photosynthetic cyanobacteria (<i>Chroococcidiopsis</i>) Possibility of photoheterotrophy by archaea with light-driven proton pumps Degradation of organic carbon by heterotrophic bacteria and archaea Genes for the 3-hydroxypropionate/4-hydroxybutyrate carbon fixation pathway in <i>Thaumarchaeota</i>	No nitrogen fixation; acquisition of bioavailable nitrogen from atmospherically-derived nitrate Genes for ammonia oxidation in <i>Thaumarchaeota</i>	Crits-Christoph et al. (2016) and Finstad et al. (2017)
Saline and alkaline soils	CO ₂ fixation through various pathways, including Calvin and reductive TCA cycles	Aerobic nitrate reduction; decreased nitrogen fixation	Hwang et al. (2020) Dendooven et al. (2010), Navarro-Noya et al. (2016) and Ren et al. (2018)
Geothermal soils	Chemolithoautotrophy, with carbon fixation using H ₂ and H ₂ S released by volcanic activity Methanotrophy from methane released by volcanic systems, occurring in soils with temperature <50 °C, pH >2.5 and low H ₂ S and H ₂ concentrations (due to competition with chemoautotrophic communities)	Nitrogenase genes detected; temperature upper limit for denitrification higher than for nitrogen fixation and nitrification	Burr et al. (2005), Gagliano et al. (2020) and Picone et al. (2020)
Deep continental biosphere (subsoil)	Primary organic carbon production by hydrogen-utilizing, autotrophic sulfate-reducing bacteria Utilization of small organic carbon molecules originating from serpentinization reactions of organic-rich graphite zones, by sulfate-reducing bacteria	Possibility of nitrogen fixation in deep subsoil, with hydrogen production	Lollar et al. (2019), Gregory et al. (2019) and Swanner and Templeton (2011)

Cold environments span more than 70% of the Earth and represent one of the largest biospheres. Microorganisms dominate these cold environments, and as such they represent the most abundant cold-adapted life forms on Earth. Among cold soils, the least hospitable are the cold desert soils of Antarctica and parts of northern Greenland. Of its 13,661,000 km², only 0.36% of the Antarctic continent is ice-free, and the ice-free areas consist primarily of permafrost. Mean air temperatures in January range from close to 0 °C in coastal areas to about -27 °C in inland zones. However, surface temperatures during summer may be much warmer. They are frequently above 0 °C for several days at a time and reach 20 °C, although wide fluctuations are common. Moisture supply is from snowfall or drifting snow, and yearly precipitation varies between 400 mm for wetter and warmer coastal areas to 20 mm or

even less in inland and colder zones. Cold desert soils have a slightly acid to alkaline pH reaction and high salinity, with salts that are principally chlorides, nitrates and sulfates of sodium, potassium, and magnesium. In comparison to Antarctica, the Arctic region climate is less extreme, supporting more plant and animal life. In both the Arctic and Antarctica, extended periods of darkness occur during winter months, while high UV radiation is experienced during summer.

Microorganisms thrive in cold climates, with phylum-level compositions of many microbial communities in Antarctic soils, occurring for example in the Dry Valleys and the Antarctic Peninsula, often equivalent to that of temperate soils. Bacterial phyla that are most abundant in temperate soils, such as Proteobacteria, Actinobacteria, Bacteroidetes and Firmicutes, are also dominant in polar soils. However, high specialization occurs at the species level, and diversity is reduced in the more extreme Antarctic environments. Microbial communities in polar soils are largely endemic and vary in distribution patterns over meter, kilometer, regional and continental scales. Various key biotic and abiotic factors, in particular pH, C/N ratio, assimilable N and phosphorus concentrations, as well as plant cover, influence polar microbial communities in these extreme environments (van Dorst et al., 2017). In Antarctic soils, many microorganisms are thought to principally exist in a dormant state, with metabolic energy directed towards cell maintenance rather than growth (Ji et al., 2017).

Many ice-free surface soils in Antarctica have been exposed for millions of years and have remained largely unchanged over that time. These soils have generally been unaffected by direct anthropogenic impacts and are often very isolated. Even if microbes can be dispersed to remote soil patches via aeolian transport, they often face a unique combination of cold temperatures, extremely low soil water potentials, and high salt concentrations that restrict the activity and survival of all but a few specifically adapted taxa. Some isolated Antarctic soils may have remained effectively uninhabited by microbes due to these constraints. Indeed, microbes could not be detected in many of the driest, higher elevation Antarctic soils, using cultivation-dependent, cultivation-independent, and metabolic assays (Dragone et al., 2020). Fungi are frequently found in Antarctic soils, including some soils from where no bacteria could be cultured.

In oligotrophic Antarctic soils, aeolian processes drive recruitment from less hostile microenvironments, and niche processes subsequently select for the most adapted microorganisms (Ji et al., 2017). The microbial community structure of Antarctic soils is shaped by selection for bacteria that can persist in these physically extreme, chemically deprived environments. Microbial phototrophs, including cyanobacteria and algae, are in low abundance, their development probably being restricted by climatic conditions such as low water and nutrient availability, summer radiation, and winter darkness. The barren soils of eastern Antarctica contain a particularly large proportion of chloroflexi, actinobacteria, and unknown, previously uncultured taxa (van Dorst et al., 2017). Most inhabitants are dormant aerobic bacteria that support energy generation and, in some cases, carbon fixation by oxidizing atmospheric trace gases. Antarctic surface soil microbial communities have the capacity to scavenge H_2 and CO from the atmosphere for use as energy sources, and CO_2 as a carbon source. Bacteria from the phyla Actinobacteria, *Dormibacteraeota*, and *Eremiobacteraeota* oxidize atmospheric H_2 and CO at rates that are theoretically sufficient to sustain the energy needs of their largely dormant microbial populations. Atmospheric H_2 and CO are dependable energy sources for dormant bacteria, as they are strong reductants, diffuse through cell membranes, and occur at low concentrations throughout the troposphere.

Primary production driven by metabolism of trace atmospheric gases in the absence of endogenous photosynthesizing organisms also occurs in other cold environments, besides Antarctic cold deserts. The Atacama Desert, in Northern Chile, comprises high-elevation volcano debris fields, with oligotrophic mineral soils. There, traces gases such as H_2 , CO and several organic C1 compounds are energy sources for chemoautotrophic microbes that then supply organic carbon to simple and low energy-flux communities (Lynch et al., 2014).

Microbial mechanisms for cold tolerance

Table 2 (see above) distinguishes three categories of mechanisms for physicochemical stress resistance. These will now be discussed in more detail for the specific case of cold tolerance.

- (i) *Environmental adaptation* occurs when psychrophilic communities selectively colonize protected niches or “refugia”, notably those provided by translucent rocks or by halites of Antarctic deserts. Rock-colonizing, also referred to as “endolithic”, microbial populations are protected from physical abrasion by wind-blown sand and buffered from rapid thermal fluctuations, despite being in equilibrium with the external temperature for much of the Antarctic year. Endolithic environments host extensive and varied microbial communities, some of which are dominated by cyanobacteria, such as *Chroococcidiopsis* and *Gloeocapsa*, Actinobacteria, Alphaproteobacteria, and *Deinococcus* spp. Others are composed primarily of eukaryotic algae, melanized fungi, lichens and heterotrophic bacteria (Cary et al., 2010; Wierzbosch et al., 2012). Composition of bacterial and fungal communities are influenced by rock type and by site-specific characteristics, such as local climate, and water abundance and chemistry (Choe et al., 2018; Walker and Pace, 2007).
- (ii) In *molecular adaptation*, genome and protein structure harbors various traits favorable to life at low temperatures. These include high G + C content, high level of redundancy in crucial genomic regions, and high genome plasticity conferred by an abundance of plasmids and other mobile genetic elements. Proteins of psychrophiles also show increased flexibility and enzymatic activity at low temperature. Differential gene expression in response to cold temperatures results in up-regulation of genes encoding cold-shock proteins. These act as regulators of various cellular processes, including transcription, translation, protein folding and membrane fluidity, thus leading to physiological adaptation (see below).
- (iii) Through *physiological adaptation*, psychrophiles increase membrane fluidity and optimize membrane function. This is achieved, for example, by increasing the ratio of polyunsaturated to saturated fatty acids in membrane phospholipids, and by inserting

carotenoid pigments as membrane fluidity regulators. To prevent protein denaturation, scavenge free radicals and stabilize proteins, cold-adapted bacteria accumulate cryoprotectants and antifreeze proteins in their cytoplasm, as well as ice-nucleating proteins and trehalose (De Maayer et al., 2014).

Fungi adapt to cold temperatures through increased production of unsaturated phospholipids in the cell membrane, maintaining membrane fluidity. Cryotolerant fungi may also accumulate cryoprotectants such as glycerol (Osborne et al., 2020). Mycosporines and mycosporine-like amino acids protect fungi against UV radiation and oxidative stress and possibly act as compatible solutes, together with trehalose, polyalcohols, betaine and proline (Gostinčar et al., 2015).

Bacteria and fungi colonizing cold soils produce a variety of pigments as a protective strategy against stresses such as low temperature, oxidative stress, and ultraviolet radiation. Carotenoids, prodigiosin, and indigoidine are examples of pigments made by bacteria and fungi inhabiting Antarctic and other cold soils. In the Antarctic deserts, rock-inhabiting fungi and certain bacteria produce melanin pigments that protect cells from extreme cold and heat, polychromatic UV radiations, extreme pH and osmotic conditions (Sajjad et al., 2020).

An abundant supply of organic carbon is required for microbial community response to temperature fluctuations in cold soils. In nutrient-poor soils, oligotrophic microorganisms remain strictly dependent on one another and thus establish temperature-independent nutritional networks. On the contrary, an abundance of soil organic carbon provides for an increased flexibility in community composition, which is then constantly and rapidly optimized as a function of current values of environmental variables.

Saline and hot desert soils

Deserts represent the single largest terrestrial ecosystem type on Earth, covering ~33.6% of the global land mass, excluding Antarctica, and are classified in terms of their aridity index, a ratio between precipitation (P) and potential of evapotranspiration (PET). This results in four desert categories: dry-semiarid ($0.5 < P/PET < 0.65$), semiarid ($0.2 < P/PET < 0.5$), arid ($0.05 < P/PET < 0.2$), and hyperarid ($P/PET < 0.05$). Hyperarid deserts generally receive annual precipitation of ≤ 70 mm and their soils display high (~ 7 to 9) pH, high salinity levels, high surface radiation fluxes, long periods of desiccation, and low water activity (Zablocki et al., 2016).

Extended periods of desiccation and oligotrophy are characteristics of hyperarid desert soils. Under these environmental constraints, microbial populations often form biofilms, where cells embedded in extracellular polymeric substance matrices are adsorbed to particle surfaces (Zablocki et al., 2016).

Within arid environments, relatively moist sites harbor richer and larger microbial communities, demonstrating the intense selective pressure of aridity (Osborne et al., 2020). However, desiccation may not be the sole or even the primary factor influencing microbial life in desert environments, where high salt and oxidizing agent concentrations are also crucial factors. An abrupt increase in water availability in hyperarid soils is extremely harmful to xerotolerant microorganisms because these cells are induced to transition from the dormant state to the metabolically active state while being exposed to attack from extreme temperature and UV radiation. In addition, excessive water causes high osmotic shock through the microbial semipermeable membrane and disturbs survival strategies adapted for limited moisture. After a heavy rainfall event in 2017 at the core region of the Atacama Desert, 75–87% of pre-rainfall species were undetectable, and no viable archaea or eukaryote were detected in undrained brines. Within the phylum *Deinococcus-Thermus*, dominance shifted from that of the order *Thermales*, who are mostly thermoresistant, to a dominance of the order *Deinococcales*, who are both thermoresistant and radioresistant (Shen et al., 2021).

Sandy deserts

Firmicutes (such as *Bacillus* and *Paenibacillus*) and Actinobacteria (such as *Arthrobacter* and *Geodermatophilus*) represent the dominant bacterial communities in the Sahara and Namib sandy deserts. Proteobacteria belonging to the four subgroups (alpha, beta, gamma, and delta) are diverse, whereas *Myxococcus* and *Azotobacter* are absent. Rhizobia occur in sandy deserts, especially strains able to nodulate the legume tree *Acacia*. Cyanobacteria are common inhabitants of sandy desert soils. For instance, the filamentous cyanobacterium *Oscillatoria* can migrate to the soil surface in response to wetting events or retreat below the surface in response to drying events (Heulin et al., 2017). Although diverse, microbial populations are limited in numbers, since microbial growth is restricted by the lack of water and oligotrophic conditions.

The absence of thermotolerant bacteria from Sahara sampling sites suggests that tolerance to desiccation is more important than tolerance to high temperature as an adaptive microbial trait to sandy desert conditions (Heulin et al., 2017).

Rocky deserts and lithic microbial colonization

The hyperarid region of the Atacama Desert receives less than 2 mm of precipitation annually (Huang et al., 2020). Together with desiccation, the intense solar irradiation limits microbial survival and growth in this environment. To overcome these extreme conditions, microbial consortia find refuge within or below rock substrates. Rock-inhabiting microbes benefit from the attenuation and filtration of the intense solar irradiation. Furthermore, lithic habitats capture liquid water from incoming fog formations and from water vapor condensation (Gómez-Silva, 2018).

Quartz, sandstone, granite, limestone, anhydrite, gypsum, ignimbrite and halites are lithic substrates that sustain microbial communities in the Atacama Desert. These niches are colonized by organisms designated as lithobionts, constituting epilithic,

endolithic and hypolithic microbial communities of unculturable members of the Archaea, Bacteria, and Eukarya domains. Abundance and diversity of the lithobionts depend on water availability, with a water gradient being established from the coastal areas to inland zones of the desert (Gómez-Silva, 2018).

Lithobiont microbial communities are usually dominated by photosynthetic cyanobacteria and contain a wide diversity of members of the phyla Actinobacteria, Acidobacteria, Bacteroidetes, and Proteobacteria. Although green algae are present and may contribute to the photosynthetic fixation of carbon, the main role in light harvesting is fulfilled by cyanobacteria (Zablocki et al., 2016).

Halites are evaporitic rocks that contain more than 95% NaCl, and as such they can be considered as poly-extreme habitats, coupling hyper-salinity with high temperatures, extremely low water activity, and high levels of UV radiation. As halites are typically colorless or white, they are partially translucent to solar radiation, and consequently photosynthesis can occur in their interiors. As a result of this photosynthetic activity, a carbohydrate-based nutrient environment exists within these rocks, which sustains heterotrophic microbial life (Gómez-Silva et al., 2019). To survive, microorganisms take advantage of the fact that halite deliquesces at an atmospheric relative humidity greater than 75%, as frequently happens due to marine fog intrusions, creating a highly saline solution in its mineral pores (Finstad et al., 2017). Microbial communities of halites are largely dominated by Halobacteriales and Bacteroidetes, together with algal and cyanobacteria species. Halite microbiomes are more similar to salt-adapted microbiomes than to those from other desert ecosystems (Gómez-Silva et al., 2019).

Gypsum rock-colonizing microbes also provide an example of an extreme survival strategy. Some cyanobacteria extract water of crystallization from this substrate, inducing a phase transformation from gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) to anhydrite (CaSO_4) (Huang et al., 2020).

Endolithic communities harbor low diversity because of the extreme nature of their natural environment, with species richness and diversity being positively correlated to the availability of liquid water (Crits-Christoph et al., 2016). Nitrogen fixation cannot be detected in these arid, high-salt environments. Because productivity and growth in these environments are very low, abiotic sources of nitrogen are sufficient to sustain the communities. It has been hypothesized that atmospherically deposited nitrate and ammonium are the main sources of nitrogen for these communities (Finstad et al., 2017).

Halophilic eukaryotes, including fungi and protozoa (Oren, 2008), also occur in hot desert soils. Protozoa may control the abundance of prokaryotes and eukaryotes in hypersaline environments (Gómez-Silva et al., 2019). Endolithic microbial communities comprised mainly of eukaryotic microorganisms, such as melanized fungi and microalgae, have been found in soil gypsum crusts of the Atacama Desert. In these communities, melanized black fungi may play a role in hydration or protection of photobionts by dissipating excessive sunlight (Wierzechos et al., 2018).

Hot soils

Volcanic and geothermal soils

Volcanic and geothermal environments are characterized by low pH, high temperatures, and gas emissions consisting mainly of CO_2 with varied CH_4 , H_2S , and H_2 contents. In these environments, CO_2 and H_2 provide carbon and energy for the assembly of chemolithoautotrophic microbial communities, which perform the cycling of carbon, hydrogen, sulfur, and nitrogen.

H_2 is an abundant gas in volcanic and geothermal ecosystems that can be used by members of the microbial community as an electron donor. The low O_2 concentrations within these soils facilitate microaerobic H_2 oxidation using oxygen-sensitive hydrogenases. Zones devoid of O_2 are sites of anaerobic H_2 consumption, for example by autotrophic sulfate-reducing microorganisms or hydrogenotrophic methanogens. Methanogens are often detected in volcanic and geothermal environments, especially in the deeper anaerobic layers of the soil.

Proteobacteria are often found in volcanic and geothermal ecosystems, and this phylum includes methanotrophic and methylotrophic bacteria. The phylum Verrucomicrobia also contains methanotrophs, such as *Methylocandidiphilum*, which grows at temperatures of 50–60 °C and at pH of 2–5. Volcanic and geothermal ecosystems remain low in organic carbon (Picone et al., 2020).

Fire-affected soils

The town of Centralia, Pennsylvania, is the site of an underground coal mine fire that has been burning since 1962. Depending on the depth of the coal bed, the fire burns at an estimated 46–69 m below the surface. Heat, steam, and combustion products vent upward through the overlying soils. As steam and gases pass through the overlying rock and soil, soil temperatures increase while soil chemical composition is altered by both spontaneous and microbial-mediated chemical reactions. As the fire expands into new areas, it also retreats from some affected sites, which then recover to ambient temperatures (Lee et al., 2017).

A comparison of metagenomes from a 45 °C gradient of temperate-to-thermal soils that lie over the ongoing Centralia coal-seam fire showed that hot soils harbored distinct communities with small genomes and small cell sizes relative to those in ambient soils. Hot soils lacked genes that encode two-component regulatory systems, and genes for antimicrobial production and resistance. The small genomes in Centralia fire-affected soils are characteristic of thermophiles that were previously dormant in the temperate soil and were resuscitated by heat (Sorensen et al., 2019). Observations from the Centralia coal fire provide examples of the priority effect from microbial seed banks, alluded to above (Section “Microbial adaptation mechanisms in extreme soils”). In any given soil location submitted to a sudden rise in temperature, individual representatives of the thermophile seed banks react with

resuscitation from dormancy and rapid growth. Identity of transitioning individuals vary from site to site, thus accounting for the multiple equilibria among communities present in the various Centralia hot soil locations (Lee et al., 2017).

Saline and alkaline soils

The World Reference Base distinguishes two groups of salt-affected soils: (i) the Solonchaks, saline soils with an electrical conductivity of a saturated extract $>15 \text{ dS m}^{-1}$ in the top 125 cm, and with values that can reach above 150 dS m^{-1} ; (ii) the Solonetz, sodium-rich soils with an exchangeable sodium percentage $>15\%$ (Zaman et al., 2018).

The Solonchaks are widespread in all the arid and semi-arid areas of North Africa, Near East, Central Asia, India, Iran and Iraq, Australia, and the Americas. The Solonetz, mainly located in the steppe climatic regimes and flat landscapes with poor drainage, exist in Ukraine, the Russian Federation, Eastern Europe, China, India, United States, Canada, Southern and Eastern Africa and Australia (Otlewska et al., 2020).

In extremely saline soils with an electrical conductivity of more than 150 dS m^{-1} , mineralization of easily decomposable C-substrate is inhibited and large amounts of NH_4 are abiotically lost through NH_4 transformation or NH_3 volatilization. Additionally, microorganisms immobilize more $\text{NH}_4\text{-N}$ than the amount required for metabolic activity (Dendooven et al., 2010).

Whereas bacterial and archaeal diversity is lower in saline soils than in normal soils, this diversity does not decrease with an increase in salinity. Thus, other factors, in addition to salinity, contribute to limit biodiversity in saline soils. For example, strong sun exposure, low precipitation and high oxidative stress may be factors common to saline soils, irrespective of salt levels (Xie et al., 2017).

Radioactive soils

Radiation (including ionizing radiation and UV-B and UV-C) occurs at very low levels in natural soils and may be perceived as a constant environmental cue essential to normal bacterial metabolism (Castillo and Smith, 2017). Despite this constantly low radiation level, resistance to intense radiation is widespread among microorganisms. At least seven phyla of Bacteria and Archaea display this phenotype, as well as a wide variety of fungi, individual species within these phyla tolerating exposures in the laboratory that are as much as six orders of magnitude higher than the annual average exposure on Earth (Battista, 2015). This extreme radioresistance may have developed as a by-product of desiccation and heat resistance (Pavlopoulou et al., 2016). Organisms highly resistant to UV-C, including strains of *Deinococcus radiodurans*, were isolated from the Sonoran and Atacama Desert soils (Paulino-Lima et al., 2016). Combinations of oxidative stress and DNA damage are induced not only by ionizing radiation, but also by desiccation, UV radiation, heavy metals, and other agents (Shuryak, 2019).

When present in sufficiently high concentrations, as occurs in Chernobyl, Ukraine, and Fukushima, Japan, soil radionuclides apply a selective pressure that can shape prokaryotic community structure (Hoyos-Hernandez et al., 2019). For example, radiation encountered in and around the Chernobyl Nuclear Power Plant led to an increased abundance of pigmented fungi, including *Cladosporium sphaerospermum* and *Aureobasidium pullulans*, some of them showing unusual adaptations such as radiotropism (Gostinčar et al., 2015). The possibility of caesium accumulation by mushrooms growing on radionuclide-contaminated soils has been investigated, because of the perceived risk of food chain contamination. Edible mushrooms may accumulate radioactive caesium from the fallout of nuclear tests to an extent that varies over several orders of magnitude, depending on the species of fungi and on the mineral composition and organic matter content of the soil (Ohnuki et al., 2019).

Subsurface environments

The deep subsurface can be inhospitable to microorganisms, with combinations of extreme temperature, limited nutrient availability and limited energy sources. Furthermore, the lack of void space often constrains microbial activity as cells require pore networks for their development and metabolism.

Despite these limitations, microorganisms persist to great depths, and hotspots of activity may occur under appropriate physical conditions, and where energy can be obtained from electron donors such as methane, iron, or hydrogen. Hydrogen gas is a highly energetic electron donor when involved in sulfate, carbon dioxide, and ferric iron reduction, among other processes. In oligotrophic deep-subsurface environments, these processes may compete against each other for a limited supply of hydrogen (Gregory et al., 2019).

Viruses in extreme soils

Reported viral abundance in soils ranges from $2.2 \times 10^3 \text{ gdw}^{-1}$ (per gram dry weight of soil) in desert sands collected from Saudi Arabia to $5.8 \times 10^9 \text{ gdw}^{-1}$ in forest soil collected from eastern Virginia. In general, viral abundance appears to be lowest in hot deserts, intermediate in agricultural soils and in cold deserts, and highest in forested and wetland soils. Soil viral abundance is positively correlated with bacterial abundance, which indicates that most soil viruses infect bacterial hosts. Temperature influences viral persistence and abundance in soils, with lower temperatures fostering the persistence of viruses and higher temperatures

promoting thermal decay of viral particles (Williamson et al., 2017). Viral abundance is positively correlated with soil pH, total nitrogen and total carbon (Narr et al., 2017).

Lysogeny is widespread among soil bacteria, with up to 40% of terrestrial bacterial populations harboring inducible prophages. Temperate phages encode repressors and transcriptional regulatory proteins that silence, not only the expression of phage genes required for lytic replication, but also expression of homologous sequences in the host chromosome. This results in downregulation of metabolic functions in host bacteria and in reduction of energy expenditure, which in turn may contribute to host survival when nutrients are scarce. Hence, lysogenic phages may play important roles in extreme soils (Williamson et al., 2017).

Cold desert soils contain large extracellular virus titers. In contrast, hot hyperarid desert soils are characterized by high levels of bacterial lysogens and low extracellular virus counts (Zablocki et al., 2016). Host-virus interactions in the Atacama Desert hyperarid core may contribute to shape adapted microbiomes in this hostile environment. Diverse viruses infect a wide range of hosts, including Actinobacteria, Chloroflexi, Thaumarchaeota and Firmicutes. Viral genomes carry putative extremotolerance genes representing other versions of genes already used by microbes in their metabolism. For example, viral genes may code DNA repair proteins, enzymes against oxidative damage, spore formation proteins, and auxiliary metabolic functions. Thus, through horizontal transfer, desert viruses could mediate the spread of microbial resilience against environmental stress. These observations are indicative of a mutualistic model of host-virus interactions in desert environments, where viruses seek protection in microbial cells as lysogens, while viral extremotolerance genes aid survival of their hosts (Hwang et al., 2021).

Biogeography of extreme soil microbial colonizers

Extreme soils are the site of coexistence between endemic specialists and cosmopolitan airborne microorganisms, with those two types of soil colonizers adept at global dispersal. Aeolian transport of microbes (Després et al., 2012) is the primary assumption inherent to the hypothesis of Louren Baas Becking that ‘everything is everywhere, but the environment selects’. Aerosolized microbes may originate from agricultural fields, sewage treatment centers, geothermal springs, any surface exposed to sufficient wind force, and large-scale volcanic eruptions. Microorganisms associated with aerosolized desert dust can be transported over thousands of kilometers, across oceans and continents. Some of the microorganisms deposited on the Mont Blanc glacier following dust storms in the Sahara Desert belonged to phylogenetic groups frequently found in polar environments, such as the actinobacterium *Crossiella cryophilus* and *Deinococcus claudionis* (Chuvochina et al., 2011). Fungal spores can be transported in the presence or absence of dust (Kellogg and Griffin, 2006). High latitude regions are also a significant source of dust in the atmosphere (Bullard et al., 2016).

While survival of cells on aeolian particles is necessary to dispersal of microorganisms, successful colonization of new habitats is also required. Given the strong selection pressure applied by defining characters of extreme soils, the composition of bacterial communities of those soils is determined more by local environmental selection than by dispersal limitation or other historical contingencies (Chu et al., 2010).

Importance of extreme soil colonizing microorganisms

Contributions of extreme soil microorganisms to climate change

Permafrost is Earth’s largest terrestrial carbon sink, trapping plant and animal material in its frozen layers for centuries. It currently stores about 1600 billion tonnes of carbon—more than twice the current amount in the atmosphere. Microorganisms that inhabit polar regions are critically involved in regulating the Earth’s climate and carbon balance (van Dorst et al., 2017). As permafrost thaws because of climate change, enhanced microbial activity is responsible for increased emissions of carbon dioxide and methane (Hultman et al., 2015). In partially thawed muddy bogs, methane is produced through hydrogenotrophic methanogenesis, involving consumption of carbon dioxide and hydrogen. In fully thawed fens, the microbial community becomes more complex, and acetoclastic methanogenesis now occurs, in which acetate and carbon dioxide are used to produce methane. These two processes react differently to fluctuations in environmental conditions (Crill et al., 2014).

Climate change is expected to accelerate dryland expansion on a global scale, leading to reduced carbon sequestration and a positive feedback loop accelerating regional warming. The increasing aridity and enhanced warming will amplify the risk of desertification (Huang et al., 2016). Studies on arid soil microbiology, including examination of nutrient cycling and modes of microbial survival, appear useful to our understanding of global biological transitions in the context of climate change.

Contributions to astrobiology

Astrobiology deals with the search for extraterrestrial life and, in so doing, is drawn to investigate the nature of life and its expressions of resistance. Extreme soil studies may fulfill three functions in astrobiology: (i) to provide analogies for extraterrestrial geological, biological, and environmental conditions; (ii) to illustrate biological processes occurring on Earth that can be extrapolated to other planets; (iii) to provide testing grounds for astrobiological research instruments, field exploration procedures, and astronaut training (Gonçalves et al., 2019).

Extremophilic microorganisms represent model organisms, useful to elucidate the possibility of existence of extra-terrestrial life. For example, studies on carbon fixation by microbial communities colonizing hot desert rocks have demonstrated that more than half of the reductive tricarboxylic acid cycle, which functions in carbon fixation, can be photochemically activated in the presence of certain metals. Thus, this pathway may be involved in a primitive form of carbon anabolism in an acidic, metal-rich reducing environment (Gómez-Silva et al., 2019). Similarly, studies on terrestrial subsurface hydrogenotrophy and of hydrogen-based microbial chemolithotrophy as it occurs in the Earth's crust provide a factual basis for speculations on the evolution of hydrogen-driven ecosystems on Mars and other celestial bodies (Gregory et al., 2019). In some circumstances, eukaryotes may show a greater degree of resistance than that exhibited by prokaryotes. Fungi inhabiting Antarctic rocks display adaptations for colonization of hostile environments, making them potentially suitable eukaryotic models for astrobiology studies. *Cryomyces antarcticus*, a psychrophilic black fungus with optimal growth below 15 °C, was isolated from rocks and soil in the deserts of McMurdo Dry Valleys in Antarctica. *C. antarcticus* shows resistance to solar radiation, radioactivity, desiccation and oligotrophic conditions, which are conditions that may prevail on Mars or elsewhere (Gregory et al., 2019).

Contributions to biodiversity conservation

Soil organisms play an essential role in supporting life on Earth. Up to 90% of living organisms in terrestrial ecosystems are associated during their life cycle with below-ground habitats. As a complex and heterogeneous system, comprising organo-mineral aggregates of different sizes and organic components, the soil creates habitats for biodiversity at multiple spatial scales (FAO, ITPS, CBD, GSBI and EC, 2020). Preserving and understanding soil biodiversity is essential to the capacity of humans at conceiving and maintaining systems for food, health, and well-being provision. Extreme soils are illuminating soil biodiversity by revealing microbial adaptations to physicochemical conditions that differ vastly from those that humans commonly experience.

Less than 1% of total bacterial diversity and 5% of fungal taxa are amenable to usual culture techniques, while the remaining organisms are only observable through metagenomics. Composition of the cultivable and uncultivable components of active microbial communities differ between extreme and non-extreme soils. Given the selection pressures that are exerted in extreme soils, observation of these differences may lead to new knowledge and to applications in a wide range of scientific, technical, and industrial fields. Although microorganisms are not commonly considered in conservation efforts, extreme soils should be considered as microbial diversity hotspots warranting protection (van Dorst et al., 2017).

Contributions to industry, agriculture, and medicine

Extremophiles and their enzymes (called "extremozymes") have the potential to mediate catalysis in a wide range of operating conditions. Consequently, they can contribute to bioremediation, agriculture, polymer chemistry, bioenergy, and various other commercial applications. Examples pertaining to various branches of human activity are provided here.

(i) Extremophiles have been used for production of bioethanol, biobutanol, biodiesel, and gaseous fuels such as methane and hydrogen (Rathinam and Sani, 2018). (ii) The electrocatalytic activity of extremophiles has been harnessed for different bioelectrochemical applications (Dopson et al., 2016). Microbial fuel cells have been developed making use of electrocatalytic activity of extremophiles for bioelectricity generation from different substrates. Electrochemical activity of extremophiles has also made possible biohydrogen production in a microbial electrolysis cell. (iii) Archaea, bacteria and fungi isolated from the rhizosphere of plants growing under extremes of salinity, heat, cold, or pH value, can potentially improve crop plant development in a context of agricultural expansion and climate change (Saad et al., 2020; Verma et al., 2017). (iv) Extremophiles are promising candidates for bioremediation of contaminated soils because of their innate potential to resist toxic environments and to degrade a wide range of pollutants. (v) Biopolymers such as polyhydroxyalkanoates, extracellular polysaccharides, and alginate have been produced using extremophiles. (vi) Pigments from cold-adapted bacteria and fungi find applications, notably as food additives and in biomedicine (Sajjad et al., 2020). (vii) Fungi and actinobacteria producing novel antitumor and antimicrobial compounds were isolated from alkaline or acid soils (FAO, ITPS, CBD, GSBI and EC, 2020). (viii) Extremozymes offer promise in a wide range of sectors including diagnostics, therapeutics, detergents, bioenergy, food processing, tanning, and other industrial applications (Rathinam and Sani, 2018). (ix) Filamentous fungi and yeasts from hypersaline environments often show metal tolerance and can be exploited for the synthesis of a variety of metal-containing nanoparticles (Musa et al., 2018).

Conclusion

Microbial colonization of extreme soils resonates in multiple manners with curiosity, technological capacities, apprehension of the past and the future, and even spirituality of humans. The ability of microorganisms to thrive in inhospitable environments leads us to expand the boundaries of life and enter uncharted territory, where life itself seems to us strange and foreign. Microbes of extreme soils invite us to a travel through time and space, to other worlds populated by life forms that seem both incipient and highly evolved. Extreme soil microbiology also brings us home, to a vast field of practical applications, such as solvent and polymer production, agricultural enhancements, pollutant removal, and clean energy production. All this occurs in infinitely complex and highly structured soil environments, creating physical, biological, and conceptual spaces for stories that in many respects resemble our own. Given the contribution of biodiversity to ecosystem resilience (Myers, 1996) and more generally to sustainability of human civilizations, we should value and preserve extreme soil-colonizing microbes.

Abstract

Organic wastes are C-rich, beneficial amendments for improving soil conditions and plant growth. However, their land application is a major source of pathogenic microorganisms entering surface and groundwater systems. Persistence and transport of these microorganisms depend on interrelationships between properties of the organic amendments and seasonally variable environmental properties of the soil. Ionic and particulate components of amendments appreciably alter the physical and chemical properties of soil and microbe charged surfaces. Microbial persistence in soils determines the load of cells available for transport. Microorganism transport depends on structure-related macropore flow and their adsorption and desorption to soil and suspended particles.

Key points

- Organic wastes are soil amendments but also major sources of microorganisms, including pathogens.
- Several interrelated factors affect survival and transport of pathogens in the soils.
- Organic waste properties can alter physicochemical properties of soils and pathogens.
- Soil type and water status play a dominant role in the fate of pathogens.
- Preferential flow and water repellency facilitate the microbial mobility.

Introduction

Organic manures and wastes are C-rich beneficial amendments used to improve soil physical and chemical conditions important to plant growth. They may improve soil aggregation and water infiltration, enhance soil water retention, decrease evaporation and the degree of compaction, increase resistance to water and wind erosion as well as soil cation exchange capacity, and serve as habitat or food source for soil life. Their dark color helps warm soils. As a source of several mineral nutrients, they can improve nutrient cycling. However, application of organic amendments to agricultural lands is a major source of pathogen microorganisms released into surface and groundwater systems. Pathogenic bacteria associated with agricultural wastes mainly include *Escherichia coli*, *Salmonella* sp., *Shigella* sp., *Campylobacter* sp., *Vibrio* sp. Pathogenic protozoans include *Cryptosporidium parvum*, and *Giardia* spp. The number of pathogens entering the environment is an important criterion for regulating the use of organic amendments in agriculture. Bacteria are single-celled organisms and constitute a large domain of prokaryotic microorganisms. Typically, a few micrometers in length, bacteria may have distinct shapes, ranging from spheres to rods (e.g., rod-shaped, curve-rods, spiral, ovoid, round or filamentous). In general, out of large totals of bacteria (e.g., 10^{10} bacterial colony forming units [CFU] per 1 g of dry matter) that can be found in manure, pathogenic bacteria commonly represent a very small percentage rarely exceeding 10^5 CFU per 1 g of dry manure. The most frequent manure carried bacteria are fecal coliforms and enterococci. Many bacteria, such as *E. coli*, are able to live under anaerobic conditions. Viruses observed in organic amendments as sub-microscopic infectious agents (30–300 nm) are able to survive outside the host for a long time. However, consistent evidence about survival and persistence of viruses in animal manures is infrequently available. Protozoa are single-celled eukaryotes, either free-living or parasitic, which feed on organic matter such as other microorganisms or organic tissues and debris.

Indicator organisms for pathogen contamination

Difficulties and expense involved in the testing for specific pathogens led to the use of indicator organisms for estimating the fate of enteric bacteria in the environment. Fecal coliforms (FC), a functional integrative category (Fig. 1), originally found in the intestinal gut of warm-blooded animals are the most commonly used indicators of pathogenic microorganisms. They are identified by their ability to ferment and produce gas from lactose at 44.5 °C.

Selected non-pathogenic strains of *Enterococcus* and *E. coli*, common and at high concentrations in manure and sewage, are also used as indicators of fecal contamination. *E. coli*, the most ubiquitous FC, is a Gram-negative, facultative anaerobic, rod-shaped (1–6 µm), coliform bacterium of the genus *Escherichia* and is commonly found in the lower intestine of warm-blooded organisms (endotherms). Most *E. coli* strains are harmless, but some strains, such as *E. coli* O157:H7 are pathogenic. Indicator organisms are selected for their easy culturing and counting but their persistence in the environment may not be the same as that of pathogens. However, the presence of a small number of indicator organisms in drinking water sources may signal a risk to human health.

The fate and survival of pathogens in soils can be affected in three ways: (1) retention in the soil matrix, (2) transport through soils to deeper layers and toward groundwater or tile drains, and (3) die-off due to unfavorable environmental conditions. Many factors may modify these including type of organic waste, pores size distribution and continuity in the soil. These soil characteristics are determined by the interplay between porosity and particle size distribution and influence permeability and

Fig. 1 The microbial pathogens in organic wastes are found in small proportions, harder to identify; thus, more common, encompassing groups such as fecal or total coliforms are used as indicators of potential risk.

water flow characteristics, as well as acidity and ionic strength of soil solution, all also affected by climatic conditions and management practices. Survival and transport of pathogens depend on the physicochemical properties of both soil and manure as well as the interactions between soil, water, microorganisms and the surrounding environment. Transport of bacteria from a diffuse field source (i.e., manure spreading) to surface and ground water bodies is mediated by precipitation, snow melt, and irrigation water.

Bacteria survival and persistence in soil systems

Enteric pathogens may survive for a long period of time outside their hosts. Numerous factors influence the survival and persistence of such pathogens in soil (Fig. 2). Survival of enteric bacteria in soil and groundwater can commonly range from 2 to 4 months. Several factors can affect bacteria survival in soil as follows: soil water status, soil type, temperature and pH, manure type and application method, nutrient availability, and competition.

Soil water status

The principal factor affecting the survival of enteric bacteria in soil systems is considered to be the soil water status or availability (i.e., soil water potential), overriding or obscuring the significance of other factors. Fecal microbes die more readily at low matric potentials in unsaturated soils. Survivability of *E. coli* or fecal coliform originating in animal manure increases as soil water content increases, with best survivability in waterlogged organic soils. While this phenomenon has been repeatedly reported, there is yet limited quantitative information to support prediction of the absolute relationship between soil water activity and microbial survival.

Soil type

Although soil type generally reflects pedogenesis, it can also be employed to infer physical and chemical properties relevant to soil biotic parameters. The single property that can be most easily related to bacterial survival is water retention, which is linked to particle size distribution and organic matter content. Reduced mortality could be primarily related to soil type, with lower mortality in soils with a higher matric potential.

Temperature

Readers are directed to the extensive review of the effects of temperature on *E. coli* die-off by Foppen and Schijven (2006). Most research reports an inverse relationship between temperature and FC bacterial mortality. Die-off rate of coliform bacteria is

Fig. 2 Factors affecting the persistence of bacteria in soils.

approximately doubled for each 10 °C increase in soil temperature. As the soil cools, survival of fecal bacteria is enhanced: 90% of coliform bacteria die-off within 3.3 days of land application in the summer compared to 13.4 days in the winter; *E. coli* could survive at least 100 days in a water-soil matrix kept at 10 °C (Foppen and Schijven, 2006).

pH

Enteric bacteria are acclimated to neutral to slightly alkaline pH ranges, similar to the conditions in the lower digestive tract of warm-blooded animals. Thus, once discharged into the soil environments, the more acidic pH reduces their survival period. If the pH matches more closely the neutral pH in excreta, survival is improved. *E. coli* and fecal streptococci survive several weeks in limestone (pH 5.8–7.8) while dying in a few days in a peat soil (pH 2.9–4.5). If other properties, such as texture, organic matter and thus water activity, are comparable, the pH will still affect microbial survivability.

Soil carbonate content

Limited research has been carried out on the effect of carbonates on bacterial survival in soil. Carbonates do affect soil pH and, especially in arid soils (i.e., subsurface caliche layers), they can also control water retention. CaCO₃ supplementation to an arid loamy soil (at up to 25% of the total soil mass) was found to reduce the persistence of nalidixic acid-resistant *E. coli* (*E. coli* NAR), especially at high temperatures (i.e., 37 °C; Farhangi et al., 2013), even at a sufficient water content (i.e., at field capacity). On the other hand, survival of *Pseudomonas fluorescens* CHA0-Rif was enhanced with increased carbonate content, at the same time as the overall activity of the microbial community declined. This was evident for high temperatures as the temperature declined the presence of carbonate did not have an evident favorable effect on *P. fluorescens* survival (Farhangi et al., 2014).

Properties of organic wastes and storage conditions

Animal manures are the primary sources of non-native bacteria introduced to soils. Concentrations of indicator and pathogenic organisms in animal manures vary widely depending on animal species, age of animals, waste storage system (liquid or solid), storage period, and level of pre-treatment prior to land disposal. Usually, the number of pathogens may first increase as manure is stored, and then may decrease. The decay rate of bacterial counts is faster in solid manure than in liquid manure. Temperature, water content and pH can affect the decay rate of pathogens during manure storage.

Type of organic waste and application method

The total counts of pathogenic bacteria are greater in swine and poultry manure than in cattle manure. Due to the greater mobility of bacteria in the liquid phase, liquid organic waste tends to be more uniformly contaminated than their solid counterparts. Methods for the land application of depend on the type of organic waste (liquid or solid), soil, and crop. When liquid waste is injected into soil, microorganisms are unlikely to be destroyed by the UV in solar radiation. Injection also increases the possibility for microorganisms to be adsorbed onto soil particles. Normal tillage used in farming operations can influence the abiotic and biotic environments that waste microbes experience after application.

Nutrient availability

Nutrient availability is central to the survival of microbes in soil. Besides its role in mediating water retention, organic matter may also increase the retention of nutrients, provide an available carbon source for heterotrophic microbes. Hence, increased organic matter contents promote the survival of bacteria and also of enteric bacteria in soil.

Competition

Competing microorganisms will limit pathogen survival in soil. Bacteriophage and predatory microorganisms, such as *Bdellovibrio*, further limit the survival of fecal bacteria in soils. In the absence of soil microbes, i.e., in sterile soil experiments, pathogen regrowth might occur. On the other hand, addition of organic waste may favor recovery of *Escherichia coli* already in soil. Macrofauna, such as earthworms, may also limit persistence in soil of enteric microorganisms.

Bacterial transport in soil systems

Critical to the distribution of contaminant fecal bacteria in the soil and water environments is their likelihood to be transported through soils. Transport of bacteria through the soil depends on flow path geometry and stability and is mitigated by interaction

between soil, soil solution, air-water interfaces, and characteristics of microbial surfaces. After initial entry, the transport through soil depends on continued entrainment of bacteria and resuspension of those retained on the porous structure (Fig. 3).

Bacterial transport through heterogeneous porous media, such as soil, is affected by the interplay of a series of mechanisms which may be divided into physical, chemical and biological. Microorganisms can migrate through soil via advection and dispersion, while being subjected to the effects of filtration, adsorption, desorption, growth, decay, sedimentation and chemotaxis. Transport and retention of bacteria and solutes in soil are largely affected by soil texture, structure and their interactions, which affect the distribution of soil water content, water flux density, pore size distribution and continuity, filtration, adsorption and sedimentation. All these complicate the description and prediction of the movement of bacteria in soil. Furthermore, the electrochemical characteristics of bacterial cell surfaces and probably bacterial shape, together with the effect of manure on the ionic and electrostatic properties of the soil solution and surfaces of the soil matrix, affect bacterial transport and retention of manure-borne bacteria. Nevertheless, the transport of pathogens and indicator organisms in soils receiving manure is mainly facilitated by infiltrating water and surface runoff and associated with the movement of sediment and waste colloidal particles.

Physical processes

Principal physical processes for microbial movement through porous media soils include convection and advection or mass flow and hydrodynamic dispersion (mechanical mixing). Bacterial transport is mostly passive, being determined by the presence of rapid water fluxes (convection) and heterogeneity in water velocity at pore scale (dispersion), although cell motility can play a role in movement in suspension over short distances. Diffusion, as a short-distance process, is of little importance in bacterial transport compared to mechanical mixing. However, diffusion may be an important transport mechanism for small virus particles ($<1 \mu\text{m}$). Filtration and straining occur when a microorganism is prevented from flowing through a pore. Sedimentation is the gravitational deposition of particles (bacteria) on soil grain surfaces.

Physicochemical processes

Physicochemical adsorption and desorption processes are mainly attenuative in nature and hinder microbial transport through soil. Adsorption is defined as the process of accumulation of charged molecules or particles that are in aqueous suspension or solution on a suitable charged surface; the interfaces between air and liquid can also act as adsorption surfaces. Adsorption of microorganisms to soil surfaces is reversible and is best described by the Freundlich isotherm.

Biological processes

Microbial processes such as growth or death affect the concentration of microorganisms, thereby affecting microbial transport measurements. Transport of microorganisms may depend on the environmentally-driven phenotypic expression of the genetically controlled characteristics of microbial cells such as size, shape, and composition of the cell envelope. Motility of bacteria was sometimes found to contribute to transport velocities under static conditions in nutrient-saturated sand and sandstone with velocities of up to 0.4 cm h^{-1} . Motile microorganisms can migrate in response to chemical gradients. Such movement, known as chemotactic migration, is a directional motion toward or away from higher chemical concentrations of nutrients or toxicants.

Transport pathways

Bacteria and viruses move through soils with the distance travelled being dependent on the soil pore characteristics. Research results summarized as early as 1975 by Gerba et al. (1975) indicated that, under saturated conditions, whereas coliforms could travel 0.6 m in fine sandy loam soil they travelled up to 830 m in sand-gravel; bacteriophage T4 travelled up to 1.6 km in a carbonate rock terrain area. Transport of microorganisms through soil can be very fast with the average velocity of microorganisms moving through

Fig. 3 Schematics of the impact of change in water content (i.e., passage from saturated to unsaturated soil conditions) on bacterial mobility and persistence.

soil greater than that of chemical tracers such as Cl or Br. This suggests mechanisms that accelerate microbial movement, and which differ from those involved in transport of soluble chemical tracers. This is attributed to preferential flow and pore size exclusion, which means that as bacterial cells are excluded from small pores, and thus micropore flow, due to their intrinsic size, they are constrained to remain in the larger pores, macropores, where water flows are fastest. Early breakthrough of bacteria, versus soluble tracers, has been confirmed for both saturated and unsaturated soils both in undisturbed and repacked columns.

Soil type (texture and structure) and preferential flow

In heterogeneous media, such as soils, bacterial transport is directly related to soil particle size distribution and texture. Bacterial cells tend to both flocculate and associate with charged surfaces, with cells rarely remaining independently suspended in the soil solution. Bacteria adsorbed by soil and organic waste colloids form colloid-bacterial complexes which create “bridges” between soil particles clogging soil pores and preventing the infiltration of other cells. Physical filtration is more likely for larger bacterial cells (0.2–5 μm) than for the smaller viruses (0.03–0.3 μm). Thus, the likelihood for soil pores to be clogged in this way depends on pore size, soil texture and aggregation, water velocity and bacterial cell dimensions. In disturbed soils, when bacterial cell size is at least 5% larger than the size of soil particles, the pores could filtrate or entrap bacteria. Straining in dead-end pores is an important process in fine-grained sediment. Water repellency of soil particle surfaces, such as can be induced by crude oil contamination, reduces attachment and enhances bacterial transport.

Thus, whereas soil texture, and associated charge properties can be used to predict bacterial movement through soils, this is more likely true for repacked or dispersed soils. In early research, well-controlled bacteria transport studies were conducted in columns filled with either glass beads or homogenized soils. Because homogenization and repacking processes destroy the natural soil structure, results obtained with repacked columns may not accurately represent the transport behavior of bacteria in the natural soils. In undisturbed natural soils, the soil structure and the aggregation dependent pore size distribution govern the effect of soil texture on contaminant transport. Reduced adsorption, a function of the reduced likelihood for bacterial cells to interact with surfaces of large pores, favors transport over retention. Thus, preferential flow due to continuous macropores and cracks is the main reason for rapid downward movement of bacteria in structured soils. In a classic example described by Smith et al. (1985), 44 to 79% of a pulse of streptomycin-resistant *E. coli* passed through a 28-cm column of undisturbed silt and silt loam soils. However, when the same soils were sieved and repacked to the same bulk density, less than 7% of the same pulse of *E. coli* passed through the columns with an equal elution volume.

Experimental observations indicate that preferential flow is the rule rather than the exception in most structured soils, and that continuous pores that are several times larger than a bacterial cell, allow bacterial transport over significant distances. Due to the preferential (bypass) flow paths that avoid the soil matrix, water can move through the soil profile faster than the mean water flux estimated by the Richardson-Richards equation. Suspended particles moved with this water flow through pores of a size that allows their passage (i.e., pore size exclusion). Therefore, suspended particles may be transported rapidly over a distance determined by the extent to which preferential pathways are continuous; namely, the extent of preferential flow has a direct influence on the distance to which particulates can be moved. In natural soils, macropores created by soil fauna (earthworms, insects, moles, and gophers) range in size from 1 to 50 mm and are usually tubular in shape. Pores formed by plant roots are also usually tubular. Cracks and fissures formed due to soil shrinkage and freeze-thaw cycles, are not usually tubular but might be significantly larger than the biopores described above. The erosive action of subsurface flows will also form natural soil pipes.

It is clear that structurally-stable fine-textured soils have greater potential for preferential flow and the rapid transport of microbial and solute contaminants than non-structured sandy soils. When fine-textured soils are disturbed, such as by tillage, the probability for interaction between bacteria and clay particles increases (i.e., increased collision rates), and the greater the clay contents, with greater surface charges, means that there is a greater the likelihood of these collisions resulting in adhesion of bacteria (increased collision efficiency). Preferential flow paths are even more important for the transport of larger cells or protozoans, such as *Cryptosporidium parvum*, that are less likely to enter small soil pores. Furthermore, in unsaturated fine-textured soil, water films and menisci are mostly connected and effectively transmit bacteria. Such observations confirm the dominant role for the physical filtration in the discontinuous pores of poorly structured soils (e.g., sands and loamy sands), whereas retention at adsorptive sites (i.e., chemical filtration) is more likely in structured, finer-textured soils. Nevertheless, when soil structure is altered, such as is common in disturbed soil columns, bacterial straining increases with clay content.

Due to variability in the transport of fecal bacteria, transport mechanisms need to be studied at both laboratory and field scales. Regularly tilling topsoil disrupts preferential flow pathways, favors pore discontinuity, and attenuates bacterial transport in soil. Thus, extrapolation of results of laboratory experiments to field conditions must be carefully considered to include multiple scales of heterogeneity due to three-dimensional flows, soil layering, interactions with native microbial communities, and temporal variations due to the transient nature of most environmental parameters. These factors usually confound the straightforward extension of laboratory results to field-scale predictions. Although controlled-system models are advantageous to understand the mechanistic details of microbial transport, field tests are required to determine whether large-scale complex environmental stochasticity may overwhelm the predictive capacity of mechanisms as described at laboratory scale.

Saturated flow transports more bacteria than unsaturated flow. More bacterial retention in the soil occurs for unsaturated flow conditions possibly due to increased area of air–water interfaces and reduced thickness of water films around the soil particles. Although most filtration occurs in the topsoil (e.g., ~20 cm), equivalent filtration was also measured for the deeper layers (e.g.,

40 cm) but this depended on variations of texture and structure down the soil profile. Under unsaturated flow, the breakthrough curve (BTC) for bacterial concentration is often bimodal with a peak immediately after application followed by a delayed, second peak. Although faster bacterial transport occurs under saturated flow, during unsaturated flow bacteria can appear earlier in the effluent than a nonreactive soluble tracer due to the pore size exclusion phenomenon.

The transport parameters can be modelled using mobile-immobile water (MIM), using attachment detachment approaches, allowing for the calculation of putative straining coefficients. Dual-permeability modelling, to account for both macropore and matrix flow, can be carried out in softwares such as in HYDRUS. Fitted attachment and straining coefficients increase with the soil clay content, and more evident if soils are repacked. Leaching from repacked columns typically produces symmetrical breakthrough curves, an indication of the dominant matrix flow. As macropores form and their proportion increases the breakthrough curves become skewed, with an early bacterial peak being followed by a long, low concentration leaching flow (i.e., tailing).

Impact of temperature

The risk of groundwater pollution due to application of liquid manure in the fall or spring has been the subject of debate. Livestock producers might prefer to apply the manure during the cold season as a means of reducing storage needs, providing more time for the application and reducing soil compaction when compared to the application on wet non-frozen soils in the spring. Due to bacterial die-off, bacterial densities in leachate after fall manure application might be significantly smaller than those after spring manure application. Nevertheless, winter application of manure is rarely recommended, as early spring excess runoff, from non-infiltrating frozen soils, may lead to manure nutrients and bacteria reaching nearby surface waters in surface runoff. Gharabaghi et al. (2015) studied the effect of ambient temperature (5 °C and 20 °C) on the saturated transport of *E. coli* NAR and Br through two soils which had been subjected to physical (freeze-thaw, and wet-dry cycles) and biological (by earthworms) weathering for 12 months. Leaching with cold water (5 °C) led to lower hydraulic conductivity and water flux and consequently enhanced bacterial filtration for both soils. Furthermore, very small values of the detachment coefficient for *E. coli* NAR at 5 °C meant an irreversible process of bacterial attachment in heterogeneous soils. Physical non-equilibrium MIM and attachment-detachment models were able to describe the BTCs of Br and *E. coli* NAR very well.

Decrease in surface soil temperature might reduce the bacterial release from manure and increase the bacterial die-off in the soil, while also affecting water viscosity.

Soil water regime

Transport fluxes in soil involve both vadose and saturated zones. Although the literature reports many field and laboratory experiments on the bacterial transport, most focus on the saturated zone transport presumably because saturated soils pose a greater risk to migration of bacteria than do unsaturated soils. Unsaturated transport is more complicated and has greater potential to remove bacteria and viruses from the flowing soil water. Water flow velocity, or more specifically pore water velocity, controls bacterial transport and filtration in soils; as the velocity of water decreases in unsaturated soils bacteria are more likely to be subjected to filtration processes in micropores and clogging in macropores necks. The opportunity for bacteria-soil interactions at lower water flow velocity also increases. Thus, retention probability, as described by collision efficiency, is largest over short distances, but eventually declines over long distances (i.e., straining rates coefficients decline with distance; Unc et al., 2012). This explains the propensity for the upper layers of soil to filter microbial cells most effectively.

Bacterial sorption and retention in soil systems

Adsorption is the main process which limits the movement of microorganisms. Bacteria are rarely free in the liquid phase of soil because most cells adhere to clay particles. Fine-grained soils, such as clays and silts, are more efficient in straining bacterial cells due to smaller pore sizes. The capacity of a soil to remove microorganisms is increased at low soil water contents and at greater soil clay contents and cation exchange capacity (CEC).

At first sight, this might suggest a repellent effect between bacteria and soil surfaces. At large electrolyte concentrations, and high thermal energy, the two surfaces can be brought sufficiently close for the short-range London-van der Waals forces to take effect. Although individually these attraction forces are weak, multiplicity of the connection points on the two charged surfaces can lead to an overall strong bonding. Presence of lipopolysaccharides (mucilage), produced by bacteria under specific conditions (e.g., starvation), may enhance their adhesion to mineral surfaces provided that the bacteria are brought in contact through other mechanisms and the contact period is long enough.

Surface charge properties of soil particles and bacterial cells

Most soil mineral and organic surfaces have a net negative surface charge. Changes in the environmental pH can change the ionization of surface groups and therefore change the electrical potential at the surface. Increase in the electrolyte concentration results in the neutralization of a greater number of charged surface loci by counter ions in the solution. This leads to smaller electrostatic repulsion forces as the electrical double layer thickness is reduced.

The charge properties of bacterial surfaces depend on the constituents of their cell wall and presence or absence of surface appendages. There are two basic organizational schemes for the bacterial cell wall: Phospholipids with negative charges, and proteins with positive charges. The relatively small amount of protein compared with phospholipids results in the bacterial wall mainly expressing hydrophobic and negative charges.

The effect of cell hydrophobicity on adhesion can be described as cell expulsion from the bulk of water and can result in large rates of bacterial adsorption at the solid–liquid interface. Hydrophobicity is positively correlated with bacteria adhesion to mineral particles, while hydrophilic strains are more likely to be found in bulk water. Hence, hydrophobic bacteria will attach to the liquid–solid interface at greater rates than would hydrophilic bacteria (Fig. 3). However, attachment is reversible, with a time scale of days or weeks. Consequently, hydrophobic strains move more slowly than hydrophilic ones, and thus any additive, such as surfactants, or changes in cell physiological state due to starvation (Borges et al., 2008), that modifies the hydrophobicity of cell surfaces will enhance transport (Liu et al., 2020). While most bacterial cells, both Gram-negative and Gram-positive, have a net negative charge, their hydrophobic character can vary within the same species or even strain.

Organic waste properties and components affecting bacterial transport

Organic wastes might affect soil physical and chemical conditions that are relevant to bacterial transport. Therefore, bacterial transport studies conducted in the absence of organic waste components may not correctly describe the transport potential of bacteria in organic waste-contaminated soil environments. Organic and inorganic components of organic wastes alter soil pH and increase salts together with soluble and insoluble organic compounds, all of which have an impact on the survival of bacteria, and hence their transport potential. Charged ions in solution can modify the electrostatic properties of both soil and microbial surfaces, altering the potential for the adsorption of microbes onto the soil. Increasing the ionic strength of the soil solution minimizes the thickness of the electrical double layer at the charged surfaces of microbial cells, of other suspended particles and soil surfaces. This phenomenon was also observed for gypsiferous soils: greater solubility of gypsum due to the presence of carbonate in the soil solution led to more *E. coli* transport in the high gypsum versus low gypsum soil (Sepehria et al., 2014).

Soluble and colloidal organic carbon components, and as well inorganic ionic compounds, can thus alter the electrochemical properties of microbial surfaces and thereby influence the likelihood that the microbes will remain in the pore water. Soluble organic compounds may compete with bacteria for retention at positively charged soil surface loci, reducing the surfaces available for bacteria sorption and enhancing bacteria repulsion. Also, soluble organic substances in the organic waste suspensions may attach to bacterial cell surfaces and diminish the water repellence of bacteria thus enhancing suspension of otherwise hydrophobic bacteria; similarly, adsorption of soluble organic compounds onto the surface of suspended organic particles will facilitate bacterial adsorption to such particles and favor their transport (Unc et al., 2012). The presence of organic particles can thus accelerate bacterial transport velocity, by as much as 10 times.

Larger, suspended organic particulates might offer surfaces for bacterial sorption which eventually facilitate co-transport of bacteria; organic electrolytes might increase the adsorption of bacteria on suspended charged organic particles. Attachment of waste-borne coliforms to soil can be inhibited in direct relation to increasing organic waste content. Greater detachment rates in the presence of waste have been reported for coliphages (Bradford et al., 2006a). Similarly, enhanced cell transport was observed for larger protozoans (i.e., *Giardia*) cells in the presence of waste material (Bradford et al., 2006b). On the other hand, large concentrations of colloidal manure compounds combined with increased ionic strength of the soil solution due to electrolytes in waste can lead to the production of larger flocs aggregating manure colloids and microbes. These flocs are then easier strained and retained within the soil pores, increasing the apparent filtration capacity of the soil. The concentration of charged waste particulates and electrolytes varies with type of waste: for example, greater ionic strength of soil solution following land application of poultry manure is more likely to increase such flocculation and thus apparent filtration. In contrast, the lower ionic strength of the soil solution after application of sewage or manure from cows can lead to more bacterial cells being transported through soil, even when the total bacterial count is smaller than in poultry manure (Mosaddeghi et al., 2009).

As with flocs, a large density of suspended organic particles might obstruct the bacteria-transmitting pores leading to more bacteria to be captured. Fibrous organic matter will encourage straining and filtration of microbes from infiltrating liquid. Moreover, bacteria survival may be extended in the presence of manure suspensions (Bradford et al., 2006a, b).

Approaches to microbial transport studies

Field studies

As indicated above, it is difficult to extrapolate results of laboratory experiments conducted on repacked soils to field conditions. Field studies are needed to explain general observations and to find solutions to specific problems, such as contamination of a well due to seepage from a nearby septic tank, or groundwater pollution because of land application of manure. Although field experiments are difficult to carry out, they are necessary to verify laboratory studies and to test conditions that cannot be simulated easily in the laboratory. An important issue is the compatibility of field results with those obtained in the laboratory. A quantitative comparison is difficult because microbial activity and mobility in the column is different from that at a field site. Thus, some researchers recommend the use of field experiments instead of laboratory soil columns to study microbial transport, as it is claimed that transport data determined from soil column experiments cannot duplicate actual soil structure in the field.

Laboratory studies

Laboratory studies increase our knowledge of microbial transport through disturbed (repacked) and undisturbed soil columns. Laboratory studies include the use of soil containers (batch) or soil columns (repacked and undisturbed). Batch experiments can examine adsorption phenomena without interference from other variables such as filtration. Repacked soil columns have been used in numerous bacterial and solute transport studies even though both the pore size distribution and pore continuity are altered. It is argued that repacked columns provide reproducibility and homogeneity, making it possible to study mechanistically different factors affecting bacterial movement in soils. The use of intact field soil columns is thus also common. While undisturbed soil cores have better predictive value for field situations than repacked ones, even relatively undisturbed columns may produce ambiguous results due to possible alteration in soil geometry during sampling. One proposed option to overcome such uncertainties is to use repacked columns that are allowed to weather before experimental use thus permitting for the natural re-formation of aggregates and pore networks which might then provide a more realistic, but controlled environment for transport simulations (Safadoust et al., 2011).

Model studies

Mathematical modelling of microbial transport through soils is an important tool in evaluating the long-term risk of undesirable microbes entering soil and groundwater and in identifying optimal sites for waste and wastewater disposal. Many mathematical descriptions of microbial transport through soils, such as attachment and detachment theory and filtration theory, were developed on the basis of the convection-dispersion equation (CDE). HYDRUS software is capable of simulating the transport of viruses, colloids, or bacteria by kinetic attachment and detachment together with filtration (chemical non-equilibrium) models. Two sorption-loci can be used to simulate sorption to solid phase and removal of particles due to attachment to air-water interface. In these models, first-order attachment coefficient (due to filling of favorable sorption sites) and first-order detachment coefficient are used to simulate the bacteria-solid interactions.

Role of new generation sequencing (NGS) for advancing microbial transport studies

While model development for microbial transport through soil has benefited from experiments with single, well-defined organisms, the advent of new generation sequencing (NGS) tools allows for population level and multispecies stochastic analysis of transport. Moreover, this can also provide insights into the transport of microbially associated functional genes (Bak et al., 2019) and thus allowing for the cell transport information to be augmented by information on the soil transfer of microbially associated functions. An observation that was possible due to NGS tools is that the microbes in the preferential flow paths, thus the ones likely to be transported, have functions distinct from microbes in smaller, soil matrix pores, which are less likely to be transported (Bak et al., 2019). Variability in probability for mobilization and transport of distinct bacterial species can also be rapidly parsed by assessing of the changes in the microbial community in soil flow via NGS tools (Dibbern et al., 2014). These examples highlight the utility of NGS tools to expand the scope of microbial transport modelling from the realm of contaminant microbiology to questions relevant to the vertical transfer of microbial functions in managed and natural soils. This creates the basis for unifying microbial transport knowledge, developed for assessing contaminant microbial transport, with the research modelling microbial processes relevant to geochemical processes.

Summary

Organic wastes, such as animal manures, are C-rich beneficial amendments used to improve soil physical and chemical conditions relevant for plant growth. However, application of such organic amendments to agricultural lands is recognized as a major source of pathogenic microorganisms released into surface and groundwater systems. We reviewed the interrelated factors affecting survival and transport of pathogens in the soil systems. Organic waste properties and components can significantly alter the physical and chemical properties of the soils and bacteria. Physiological state of bacteria cells can also affect their electrostatic surface properties. Soil type and water status play a dominant role in the fate of pathogenic microorganisms. Preferential flow due to soil structure and water repellency facilitate the bacterial movement through natural soils in the environment.

Abstract

The chapter addresses the source materials for composting processes, the microbes and phases involved in the process and quality criteria for composts. The focus is on composting in its common meaning, and two fauna-driven processes involving compost worms and the black soldier fly. Further, some inorganic amendments like biomass ashes and biochar are discussed. Ultimately, the overall effects of composts on soil, its microbiota and plants are discussed, and put in context with carbon mitigation and climate effects.

Glossary

Frass In natural environments, frass describes the excreta of insects. From the perspective of insect farming, however, frass is defined and marketed as an inhomogeneous mixture of feeding substrate residues, insect feces and body parts, exuviae, and dead insects that is collected after separating the harvest-ready insects at the end of the rearing process. Frass application introduces beneficial microorganisms to the soil and its chitin fraction is considered a resistance-promoting agent for plants.

Key points

- Substrates for composting processes
- Microbial vs. faunal-driven composting

- Effects of composts on soils, their microbiota and plants
- Composts for mitigation of climate warming

Introduction

In the context of global warming and a renewed debate on fossil energy, sustainable agricultural, horticultural and silvicultural approaches are receiving more attention. Indeed, the recycling of carbon (C) and nutrients to soil may alleviate the extensive use of fossil resources. Apart from rendering the soil as a sink for C, we should keep in mind that ~2% of the global anthropogenic energy use is attributed to the Haber-Bosch process to collect nitrogen from the atmosphere. With increasing prices for fertilizers, organic amendments such as manures or composts are becoming more attractive as sources of nutrients and organic matter.

Soil degradation as a result of extensive agricultural or horticultural use, combined with poor management, remains a major concern and often related to the loss of organic matter and a low level of nutrient availability. Composts may either be incorporated into the soil or used as mulch. Both approaches have advantages and disadvantages. Often, the effects are best detected in the vicinity of the applied material, which is of practical interest as roots grow toward such hotspots where they take immediate advantage of the nutrients released from the composts (Duong et al., 2013).

Definition of composting (process) and of compost (product)

Etymologically, composting (from Latin, *compositum*, mixture) refers to a biodegradation process, not of a single material but of a mixture of substrates. In addition, the process is carried out by a mixed community of organisms, be they only microorganisms, or microorganisms and fauna. The microbial conversion of pure substrates would be called fermentation or bio-oxidation, but not composting. Composting is commonly carried out on the basis of solid substrates (also rich in lignocelluloses), and is generally understood as an aerobic process. The exothermic process generates energy in the form of heat, resulting in an increase in temperature. A spontaneous process characteristically goes through five phases, an initial mesophilic phase, followed by a thermophilic and subsequent cooling (second mesophilic) phase, maturation and a terminal curing phase. During composting a temporary release of phytotoxins (intermediate metabolites, ammonia, etc.) is typical, while in the terminal phase this phytotoxicity is overcome and the end product benefits plant growth. The composting process results in CO₂, water, minerals and stabilized organic matter (often referred to as 'humic' material, a concept that has, however, been challenged by Lehman and Kleber, 2015). In brief, composting is based on a mixture of substrates and degrading organisms, particularly microorganisms, and is characterized by a constantly changing physico-chemical environment, including nutrient availability, pH, temperature and composition of intermediates (Insam and De Bertoldi, 2007; Insam et al., 2002). Although some authors term anaerobic treatment (in particular biomethanization) anaerobic composting, this process is explicitly not covered in the present chapter. The end product of anaerobic processes is called digestate, and does in many respects have different effects on soils than do composts (Gómez-Brandón et al., 2016). Post treatment of digestates by composting, however, may well be used to stabilize the material, again resulting in a product termed compost.

The main product of the process is called compost, which can be defined as stabilized and sanitized, compatible with and beneficial to plant growth. The conversion of waste organic material into compost is carried out for three main reasons, (i) to overcome the phytotoxicity of fresh, unstabilized organic material, (ii) to reduce the presence of pathogens (viruses, bacteria, fungi, parasites pathogenic to humans, animals and plants) to a level that does not pose a further health risk, and (iii) to produce an organic soil amendment that serves the purpose of nutrient addition and physico-chemical conditioning. This way biomass in the form of organic waste and crop residues is recycled.

Scope of this chapter

There is a plethora of different methods of composting, ranging in size from miniature backyard to huge industrial operations, and involving many different substrates from agricultural residues to kitchen waste and municipal sewage sludges. There are rapid processes, and others that take more time; there are pure microbiologically driven processes and ones that exploit the activities of mesofauna. In this chapter there will be a focus on medium- to large-scale, farm-scale and commercial composting, as well as on vermicomposting and organic waste treatment by the black soldier fly.

The substrates

Basic for any composting process is the availability of degradable organic matter which is usually of plant origin, but may also stem from faunal tissue or microbial cells. The basic materials are presented below, each with its own properties for the process. Owing to the biochemical composition of the substrate material, the composting process runs differently, and also the resulting compost quality may be different. Basic substrates range from manure or other agricultural or agro-industrial residues, to domestic organic

waste from source-separated collection and slurries from wastewater treatment plants. Also, mixtures of such wastes are often used, including lignocellulosic materials (bush- and tree cuttings), which serve as bulking agents, or digestates from biomethanization plants.

Cellulose

Cellulose as the most abundant component of plants is found in many types of organic waste. Waste rich in structural elements (such as wastes from the wood industry and straw from agriculture) has the highest cellulose content, while domestic organic (kitchen) waste contains less, and wastes derived from microbial or animal sources contain no cellulosic material. Cellulose molecules are chains of β -1,4-glycosidic bonded glucose with a polymerization degree of up to 40,000. Enzymatic degradation is brought about by the activity of three enzymes, (i) Endo- β -1,4-glucanase, (ii) *exo*- β -1,4-glucanase and (iii) β -glucosidase, the resulting glucose is taken up by the microorganisms and used for energy and as base molecules in anabolic processes.

Many fungi and bacteria are involved in the breakdown of cellulose. The catalytic effect (mechanical destruction) of micro- and mesofauna may be an important contributing factor. Fungi are generally more important than bacteria in breaking down cellulose, especially when cellulose is encrusted in lignin (e.g., in straw or wood). Because cellulose is rich in C but lacks N or other essential elements, the hyphal structure of fungi has a competitive advantage as the hydraulic force of fungal hyphae can break up lignocellulosic material. *Chaetomium*, *Fusarium* and *Aspergillus* are important fungi to mention in this context; cellulose-degrading bacteria mainly belong to the Myxomycetes or related classification groups (*Cytophaga*, *Polyangium*, *Sorangium*). *Pseudomonas* and related genera are also known to degrade cellulose, as are Actinobacteria.

Lignin

Lignin is a most recalcitrant structural component of plants, making up 2–30% of their biomass. It is composed of few monomeric units (phenylpropane derivatives, mainly coniferyl and sinapyl alcohol) but, due to the extraordinary variety of chemical bonds involved, its degradation is complex and yields little energy. Very often, the degradation of lignin is of a co-metabolic nature, primarily accomplished by fungi, in particular white-rot fungi such as *Trametes versicolor* or *Stereum hirsutum*. They break down the lignin, leaving behind cellulose parts that are light in color. Some fungi, such as *Pleurotus ostreatus*, degrade both cellulose and lignin.

Hemicelluloses

Among the hemicelluloses, xylan is most important, found in straw, bagasse and wood. It contains pentose sugars, such as arabinose and xylose, as well as hexoses, including galactose, glucose and mannose with a degree of polymerization of 30–100. Pectin, made up from unbranched chains of polygalacturonic acid, is degraded by pectinase, commonly produced by fungi and bacteria. Starch contains amylose (20%) and amylopectin. The former are unbranched helical (due to 1,4-position β -glycosidic bonding) chains of α -glucose, while the latter, containing phosphate residues and Ca and Mg ions, is also branched at the 1,6-position. Two types of enzymatic degradation are important, phosphorolysis (releasing glucose-1-phosphate) and hydrolysis (α -amylase cleaving the α -1,4-bonds within the molecule).

Chitin

Cellulose and chitin are chemically very similar. In chitin, glucose is replaced by N-acetylglucosamine, which makes a difference for degraders since chitin contains approximately 7% N (C:N-ratio = 7). Many fungi and bacteria use chitin both as an N and C source. Chitin is degraded to N-acetylglucosamine, which is resorbed, transformed to fructose-6-P and channeled into the carbohydrate metabolism. Chitin is an important structural compound in fungal cell walls, makes up the exoskeleton of crustaceans and insects, making it an important waste product from pharmaceutical and shellfish industries.

Murein

Murein, consisting of unbranched chains of N-acetylglucosamine and N-acetylmuramic acid bound to variable amino acids. Murein is the main cell wall component of most bacteria, and thus only a minor component of most waste streams. It may, however, be an important component of wastes derived from the pharmaceutical industry, and in wastewater slurries.

Other compounds like collagen or keratin

Proteinaceous compounds stemming from animal wastes serve as slow-release nitrogen sources and contribute to the value of the resulting compost. Often, they are contained in the digestates of biogas plants that are using slaughterhouse wastes.

Supplements

The supplementation of composts with by-products, such as biomass ash (Kuba et al., 2008; Bougnom et al., 2010) and biochar (Agegnehu et al., 2017) serves two purposes, the reduction of waste and the improvement of the product. Biomass ashes provide major nutrients like phosphorus (P), a multitude of micronutrients and also serve as a lime replacement, while biochar provides exchange sites, micro-niches for microorganisms and improves the physical structure of composts. There is consensus that the mixing of composting substrates and supplements prior to the composting process adds additional benefit compared with mixing prior to soil amendment. Other supplements, such as rock dust, are known for similarly positive effects, mainly through providing nutrients and facilitating the formation of mineral-organic complexes (aggregates). It has been reported that not only the soil microbiome is changed, but the effects extend as far as improving the vitamin C content in apples (Li et al., 2021).

The organisms and process phases

The commonly recognized composting at farm- and industrial scale

In contrast to small-scale backyard processes, larger scale operations do usually not allow for micro- or mesofauna driven processes, but rely on purely microbially driven turnover. This is because of the speed of the process (6–12 weeks) and the need for mechanical disturbance by either periodic or continuous turning. Such operations mostly rely on a well-designed process regulation based on measurements of carbon dioxide or oxygen content, temperature, pH and moisture. Also, pretreatment of the substrate material, including cutting, milling and sieving plays an important role, as does active or passive aeration, and moisture control. Five phases are typically involved (Fig. 1).

Initiation phase

In this first phase (also called starting phase or first mesophilic phase), easily degradable compounds like sugars and proteins are abundant and are initially degraded by mesophilic or thermotolerant (20–35 °C) fungi and bacteria, including actinobacteria. Ryckeboer et al. (2003) found few mesophilic fungi in source-separated household waste, but numerous thermophilic fungi and bacteria. Initially, food wastes containing vegetable residues often have a low pH (4.5–5.0) that stimulates the proliferation of fungi and yeasts. Ammonification causes an increase in pH, favorable for bacteria that subsequently colonize the substrate. Wastes that are rich in lignocellulosic matter show a different composition, still with a high microbial diversity but having a bias toward fungi.

Fig. 1 Biomass, temperature and pH as they typically evolve in a composting process. The graph also shows dominant microbiota at two stages, as well as main material conversions.

However, due to the more rapid growth of bacteria, and a metabolism-driven temperature rise, fungi and yeasts are soon outcompeted. The high surface:volume ratio of bacteria allows a rapid transfer of soluble substrates into the cells. Bacteria are taxonomically and nutritionally the most diverse group, equipped with a broad range of enzymes to degrade a variety of organic materials. Also, the bacterial generation time is much shorter than those of fungi, which gives them a competitive advantage. Actinobacteria tend to grow slower than many other bacteria and are ineffective competitors when nutrient levels are high (Beffa et al., 1996); they thrive, however, as soon as the most easily degradable substrates are exploited. Due to their ability to produce various antibiotic substances, actinobacteria (e.g., streptomycetes) are most important for hygienization, inhibiting the growth of many human, animal and plant pathogens. If mechanical influences (like turning) are very limited, fauna, such as compost worms, mites, millipedes, and mesofauna develop, which mainly act as catalysts through their ability to physically disrupt substrates. Important regulators of microbial activities are protists, as well as viruses, including bacterial and fungal phages.

High temperature phase (35–65 °C)

When process temperature rises, thermophilic and thermotolerant organisms get a competitive advantage and gradually replace the mesophilic biota. Previously flourishing mesophiles die off and are eventually degraded by the succeeding thermophiles. Overall bacterial species diversity falls significantly during the thermophilic phase. The number and diversity of thermophilic actinobacteria increases, however, particularly at temperatures of 45–55 °C (Amner et al., 1988; Beffa et al., 1996). The decomposition runs fast and accelerates temperature increases up to about 62 °C. The rise in temperature is another reason why bacteria outcompete fungi. Temperatures exceeding 60 °C inhibit fungal growth, but they may survive as spores. Yeasts disappear during the thermophilic phase, but when the temperature cools down to 54 °C, they reappear (Ryckeboer et al., 2003). Endospore-forming bacteria, such as *Bacillus stearothermophilus*, are often considered typical for composting processes. They are very active at temperatures higher than 50 °C or even 60 °C (Ryckeboer et al., 2003). Non-spore forming bacteria such as *Hydrogenobacter* spp. and *Thermus* spp. are among the dominant ones in the hottest phase of the process, active at temperatures >70 °C and up to 82 °C.

Thermal inactivation of pathogens is required to obtain safe products, both in terms of phytohygiene and human diseases. The higher the temperature, the more efficient will be the destruction of pathogens (Ryckeboer et al., 2003) albeit temperatures exceeding 80 °C may trigger the Maillard reaction, leading to undesired odor and microbial inhibition. Millner et al. (1987) showed that pathogen suppression was more efficient in composts produced at 55 °C than at 70 °C. Additionally, regrowth of mesophilic populations may be delayed if too high temperatures are maintained for a long time and if this temperature is reached throughout the composting material, calling for appropriate reinoculation schemes.

Cooling phase

As soon as the easily available substrates are exhausted, the temperature starts to decrease. Mesophilic organisms recolonize the substrate, originating from surviving spores, through spread from protected microniches, or airborne inoculation, or as organisms attached to turning or sieving machinery. In this medium-temperature phase the available substrates are much different to those in the first low temperature phase. They are largely dominated by secondary degradation products, and recalcitrant polymers, such as starch, cellulose or lignin, and also thermally inactivated microbial cells.

Maturation phase

Lignin, cellulose and other recalcitrant compounds are decomposed by specialized microbiota equipped with ligninases, peroxidases and cellulases. The maturation phase is important for the build-up of humic acids that are either generated from aromatic compounds derived from the lignin, or are synthesized de novo. The humic matter is among the most valuable components of composts. During maturation, fungi are starting to outcompete bacteria, of which *Arthrobacter* form a numerically important fraction. Species diversity seems to be correlated with stability of the end product (Beffa et al., 1996). After incorporation into soils, immature composts may induce enhanced microbial activity and cause oxygen deficiency and a variety of phytotoxicity problems to plant roots.

Curing phase

Some researchers refer to a post-maturation, so-called, curing phase. In this phase, it is hardly possible to diagnose changes in physical or chemical compost quality. However, changes in the microbiota may still occur to the benefit to the product (Danon et al., 2008) but also to its disadvantage, for example, because of decreased plant disease suppressiveness (Franke-Whittle et al., 2019).

When is compost mature?

Classical maturity tests are discussed in detail by Itävaara et al. (2002) and Insam and de Bertoldi (2007). Benefits of compost application, such as suppression of diseases caused by soilborne plant pathogens, have been reported in agricultural and horticultural crops. Composts in their early stages often exert phytotoxic effects that may be associated with ion concentrations,

Table 1 Rottegrad, definition of process conditions.

Rottegrad	T_{max} in °C	Product
I	>60	Fresh compost
II	50–60	
III	40–50	
IV	30–40	Mature compost
V	<30	

excessive availability of heavy metals, toxic organic compounds or an adverse phytopathogenic microbiota. Phytotoxicity is defined as a delay of seed germination, inhibition of plant growth through, e.g., phytotoxins. During compost maturation these effects are commonly alleviated, rendering the composts compatible with plants and plant roots. Compost maturity tests based on phytotoxicity is a well-established methodology, worldwide (Bernal et al., 2017), as are tests based on ammonia or carbon dioxide release, or self-heating tests in Dewar flasks (Rottegrad test; Table 1) (Itävaara et al., 2002; Changa et al., 2003).

Vermicomposting

In general, small-scale composting favors faunal-driven composting, in contrast to large-scale operations that favor microbially dominated processes. Only in special cases, like vermicomposting or black-soldier-fly (BSF) driven operations, does large scale also enable a faunal-driven process.

Unlike composting, vermicomposting does not include a thermophilic phase and relies on the synergistic actions of earthworms and microorganisms to accomplish the breakdown of the organic matter. Earthworms have been classified, on the basis of their feeding and burrowing strategies, into three ecological categories: epigeic, anecic and endogeic. In particular, five epigeic earthworm species have been extensively used in vermicomposting facilities known as *Eisenia andrei* (Savigny), *Eisenia fetida* (Bouché), *Dendrobaena veneta* (Savigny) and, to a lesser extent the tropical species *Perionyx excavatus* (Perrier) and *Eudrilus eugeniae* (Kinberg). These earthworm species live in the soil organic horizon, in or near the surface litter, and mainly feed on fresh organic matter contained in forest litter, litter mounds and herbivore dung, as well as in man-made environments such as manure heaps. All display a natural ability to colonize organic wastes and are characterized by short life cycles, high reproductive rates and a high rate of consumption, digestion and assimilation of OM.

Vermicomposting systems sustain a complex food web that results in the recycling of organic matter (OM) and the release of nutrients (Domínguez et al., 2010). However, more than a century passed before vermicomposting was considered a viable technology, despite the important role of earthworms in the decomposition of dead plants and nutrient cycling. During vermicomposting, epigeic earthworms and microorganisms intensively interact accelerating the stabilization of OM and greatly modifying its physical and biochemical properties. Although microbes are responsible for the biochemical decomposition of the OM via the production of extracellular enzymes, earthworms are key players in the process through their effects on microbial communities. They may influence microbial decomposer activity by grazing directly on microorganisms, or by increasing the surface area available for microbial attack after the comminution of organic matter. Earthworm activity favors the aeration and fragmentation of OM, thereby enhancing its turnover and increasing the rate of decomposition. They can also affect other fauna directly through the ingestion of microfaunal groups (protozoa and nematodes) that are present in the detritus consumed, or indirectly by modifying the availability of resources for these groups.

In the short-term, the earthworm gut-associated processes, that is the ingestion, digestion and assimilation of OM and then casting, are major drivers of the vermicomposting process. Earthworms excrete large amounts of egested materials known as casts that result in an inoculum of nutrients and microorganisms into the environment. The contact between these materials and the raw substrate has been found to alter the nutrient dynamics and the rate of OM decomposition, similar to that when earthworms are present. The changes occurring during these initial stages of vermicomposting largely determine the properties of the final product and its potential usefulness as an organic amendment. A period of aging is also necessary to obtain a mature, phytotoxic-free vermicompost for its proper use to promote plant growth and suppress plant diseases. The duration of the maturation phase is not constant and may vary depending on how efficiently the initial phase of vermicomposting is performed.

Vermicompost is considered a nutrient-rich, peat-like material characterized by a large porosity and water holding capacity, but a small C:N ratio. Beneficial effects of vermicompost have been documented for a wide variety of agronomic and horticultural crops, when used as an amendment for soil or plant growth media. These positive effects have also been reported for extracts and teas made from vermicompost (Gómez-Brandón, 2015), even though they do not impart the same physical properties as solid vermicompost. Various factors such as an improved availability of air and water, the presence of plant-growth regulating substances, and the mitigation or suppression of plant diseases have been proposed as plausible, albeit not exclusive, mechanisms by which such improvement is achieved. There is also evidence of microbial-based mechanisms that may explain the positive influence of vermicompost on soil and plants (Gómez-Brandón et al., 2020). Compared with the initial substrate,

the resulting vermicomposts exhibited a greater functional diversity and higher abundance of putative genes related to specific metabolic processes, i.e., biosynthesis of antibiotics or plant hormone synthesis, potentially beneficial for plant growth and development.

Black soldier fly composting

Insects are increasingly gaining scientific and economic interest as agents for organic waste management. In terms of fertilizer production, converting organic waste into a stable soil amendment follows a similar principle as vermicomposting. In contrast to earthworms, however, industrially used insects are not primarily seen as producers of compost but rather as bioreactors capable of transforming low-value substrates into a source of value-added products that include protein, fat, chitin, and they also yield a by-product with fertilizing properties. Most of these products are directly derived from mechanically or chemically processing the raw insect biomass. The residue fraction, however, accumulates as the major by-product of the rearing process and has recently been defined by the European Commission as a mixture of digested and undigested substrate wastes, shed skins, and also to the smaller portion of dead insects. The beneficial effect of insect droppings on soil nutrient dynamics and their effect on soil respiration was described in detail in the past. With the emergence of insect farming, these benefits are now being exploited on an industrial scale. Thus, the term “frass,” originally used to describe these insect droppings in natural environments, has been adopted to include the rearing residues and is nowadays commonly used to describe this complex insect-derived compost.

Among the few species approved for commercial insect farming in the EU, the black soldier fly (*Hermetia illucens* Linnaeus, Diptera: Stratiomyidae) is considered the most promising contender to drive the worldwide expansion of this emerging industry. Also, in natural environments, the progressing globalization and increasing average temperature contribute to the cosmopolitanism of this subtropical fly, thereby driving its dispersion across all continents except Antarctica. In recent years, efforts were mainly directed toward determining organic waste streams from industries that are suitable for bioconversion by black soldier fly larvae (BSFL). Primarily agro-industrial by-products (e.g., wheat bran, spent grains) or fruit and vegetable wastes find current application in Western countries. Due to the novelty of large-scale insect farming, legal restrictions, and immature research on the safety of insect-derived products limit the use of a broader variety of substrates that would otherwise also include animal manure or food wastes (Liu et al., 2022).

In contrast to compost, which typically matures from an inconsistent and diverse mixture of organic wastes into a largely homogenous product with comparable properties, most of the frass physicochemical properties and nutrient content vary markedly according to the rearing substrates employed (Klammsteiner et al., 2020). Therefore, the blend of organic compounds making up the rearing substrate must be well described and available in consistent quality to ensure efficient production, as the ratio of its ingredients will consequently determine the quality and fertilizing properties of the frass. The conversion of substrate into insect biomass results in a reduced N and P content in the residues compared to the original material, though the bioavailability of the nutrients is increased through insect digestion. Commercial frass from BSFL shows on average an N:P₂O₅:K₂O ratio of 1:0.9:1.1 with a relatively high C:N ratio of 14.7 (Gärtling and Schulz, 2022). In comparison with other insect species, BSFL frass contains significantly larger concentrations of N (<130%) and K (<190%) (Beesigamukama et al., 2022). Although BSFL can thrive in a wide range of pH levels, the pH in frass is among the few parameters that show little variation across production systems and starting substrates (Gärtling and Schulz, 2022). Even frass from initially acidic substrates (pH 4) becomes alkaline (up to pH 9) during the process, approximating the high pH in the larvae's posterior gut (Bonelli et al., 2019).

Frass from BSFL also induces a higher germination rate and germination index than rearing residues from other industrialized insect species (Beesigamukama et al., 2022). This might be favored by the presence of plant growth-promoting rhizobacteria and other beneficial microbes (Barragán-Fonseca et al., 2022). The frass itself has been shown to have inhibitory effects on multiple plant pathogens and shows insecticidal properties (Vickerson et al., 2015). This effect is supported by the innate microbiota of the frass, in which the microbial community becomes more similar to the one inhabiting the BSFL guts as more and more of the substrate is digested (Gold et al., 2020). Especially bacteria (Gammaproteobacteria and Bacilli) and fungi (Ascomycota) present in the frass support the larvae in degrading the organic matter by driving aerobic fermentation (Barragán-Fonseca et al., 2022). This process could be further improved by inoculating the substrate with specific species such as *Bacillus subtilis*, as supplementing these bacteria is capable of enhancing frass maturation, seed germination, and enzymatic activity (Xiao et al., 2018). Unlike compost and vermicompost, frass also contains substantial amounts of chitin from insect skins and exuviae which not only serve as source of plant nutrients, but also enhance plant defense mechanisms by positively stimulating the soil microbiota (Barragán-Fonseca et al., 2022). While the inactivation of pathogenic microorganisms and phytotoxins in compost relies on one or more thermophilic phases, pathogens in BSFL frass are inhibited by antimicrobial peptides excreted by the larvae (Klammsteiner et al., 2020). To ensure the biological safety of frass, a first legal standard that requires a 70 °C heat treatment as post-processing measure has been recently introduced by the EU commission. To achieve this, frass could either be dried or composted prior to commercialization or soil application. However, frass that was treated via aerated composting was shown to cause 20% higher greenhouse gas emissions compared to its direct use, but could offer a feasible way to enhance nutrient availability and biosafety (Song et al., 2021). Any such post-treatment of frass, however, counteracts the very positive effects of untreated frass, as explained above, and a re-evaluation of the respective EU legislation.

Several studies ranging from pot to field scale indicate that frass application can achieve similar yields as common nutrient application regimes, however, with less negative consequences for the environment than, for example, manure (Liu et al., 2022).

Current environmental challenges associated with the use of manure or inorganic NPK fertilizers such as increased leaching or eutrophication could be alleviated by supplementing or partially substituting them with frass. At field-scale, a combined use has shown to enhance crop yields and reduce losses from plant diseases due to the promotion of several plant defense mechanisms (Barragán-Fonseca et al., 2022). With further expansion of the insect farming sector and additional efforts for standardizing rearing substrates and rearing systems, the high variation in macro- and micronutrients in frass is expected to decrease. N and P can be recaptured from the food chain by integrating these residues as biofertilizers in agriculture, thereby closing nutrient and material cycles according to the principles of the circular economy.

The products

Added value, carbon and nutrients

Beyond the delivery of nutrients, most of them in a slow-release-form, composts confer numerous additional benefits to soil that range from increased soil C stocks and increased water holding capacity to plant disease suppressiveness. All the effects of composts, however, are determined by the available input materials, and the prevailing process conditions. Thus, the above mentioned three levels of control, quality of input materials, process and end product, are required for reproducible end products with their distinct effects on soils and plants.

Method of quality assessment

Compost quality is defined both by the quality of the input material and the resulting end product, as well as by the process conditions. The composting process is designed to secure an 'end-of-waste status' for the substrates. Input material, ranging from lignocellulosic wastes to wastes with a higher proportion of proteins, sugars or other short-chained carbohydrates (see above), have inherent elementary properties. Apart from nutrients and C, they these also may contain heavy metals and xenobiotics and human, animal and plant pathogens. In particular, maximum allowed heavy metal contents are regulated, both in the substrate sources and in the end product in case of a destined use in agriculture, horticulture or forestry. The legal conditions, however, vary from country to country. For xenobiotics and pathogens, the composting process is critical for their elimination. Thus, process conditions are often strictly defined, such as the process temperatures that must be reached.

Effects on soils

An advantage of compost over mineral fertilizers is its ability to slowly release nutrients into its environment, often in line with plant needs, which increase as spring temperatures rise. As soon as the soil warms up and the plants start to grow, the activity of the microorganisms that release the nutrients also increases. Slow-release mineral fertilizers were thus developed to give mineral fertilizers this beneficial property, inherent to organic fertilizers. A disadvantage of compost is that the entire nutrient content is not released in the first year of use, but only fractions of it, which complicates the annual calculation of requirements (Insam and Merschak, 1997).

In addition to the nutrient content, compost has other properties that makes it valuable: compost improves the condition of the soil. It has a favorable influence on soil structure and soil texture (Fig. 2). As a result, nutrients, water and air are better retained, which ultimately increases yields in horticulture and agriculture.

In good soil, sand, clay, and loam mix together into aggregates that allow aeration and drainage. Ideally, the earth is granular and crumbly; a large sand content makes the soil too coarse-grained but with a high clay content it may be too compact. Too much clay

Fig. 2 Visualization of the effects of compost addition on the physical and microbiological properties of soil aggregates. Left: depleted soil with poorly developed pore structure and microbial diversity, right: soil that has received compost: formation of stable soil aggregates hosting pores of various sizes and an enhanced microbial diversity.

can promote waterlogging and the soil becomes impermeable to air. Compost creates pores of various sizes that fill with air and water, rendering them available for microbial metabolism and microbe proliferation, ultimately offering an ideal substrate for plants. On the other hand, if the soil is too sandy, the water drains away too quickly. In this case, the addition of compost contributes to the formation of larger granules that are surrounded by a film of water on their surface. The addition of compost compensates for a high proportion of sand or clay and promotes the formation of aggregates (clay-humus complexes). Between these aggregates, large and often air-filled pores are maintained that allow diffusion of air (oxygen) into the soil and the outward diffusion of CO₂. Compost amendment has also shown to change the pattern of emitted volatile organic compounds (VOC) (Seewald et al., 2010).

The greater the proportion of decomposed organic matter in its various stages protected from further decomposition, the larger is the water holding capacity of the soil, which counteracts the risk of desiccation, since 100 kg of humus are able to store 195 kg of water. The storage of water can counter the leaching of valuable minerals in drainage. If a soil is subject to chemical fertilizers over a long time, it loses its structural properties. Remedial tillage, fertilizers and irrigation must be used more. Maintaining a healthy soil structure is also a protection against erosion. Good soil structure also ensures optimal ventilation; oxygen promotes the uptake of potassium by plants and enables the synthesis of SO₂, CO₂ and the conversion of ammonia to nitrate.

Another positive influence of compost is its ability to neutralize toxins. Organic matter has a large capacity to bind heavy metals. Insoluble, stable complexes are formed that cannot be absorbed by the plant and are thus withdrawn from the food chain. Gómez-Brandón (2015), Kranz et al. (2020), and Ryals et al. (2014) provide the basis for an overview of the effects of compost (including vermicompost and compost teas) on plant growth and soil fertility, which may be summarized as follows:

- Enhanced nutrient retention
- Carbon sequestration
- Reduction of bulk density
- Enhanced water holding capacity, infiltration, hydraulic conductivity and plant available water
- Improved aeration (beneficial for both microorganisms and plant roots)
- Increased microbial diversity
- Increased plant disease suppression
- Enhanced resilience toward disturbances (high or low temperatures, drought)
- Decreased susceptibility to water and wind erosion
- Immobilization of cations, including heavy metals, rendering them unavailable to plants

The difference between inorganic and organic fertilizers on the one hand and compost on the other, is the dynamics of nutrient release. This may, depending on the composition of the fertilizers, be uncontrolled and fast, but it may also be retarded owing to specific formulations. The nutrient release dynamics of composts is mostly not as well defined, and depends a lot on the C:N:P-ratio and on the maturity of the compost. However, it accords quite well with plant demand because the nutrient release depends on the activities of microbes and microfauna, which are regulated by temperature and moisture availability, as is plant growth and nutrient uptake. The fertilizer effect of composts is often disputed, and indeed, it has been shown that a combination of slow-release compost with fast release fertilizer may be a way to combine the benefits of both (Ros et al., 2006). The high-nutrient component does not necessarily need to be mineral fertilizer, but could also be a fast-release organic fertilizer, such as manure. The choice of mineral or organic forms of nutrients could be based on whether the soil was dominated by bacterial or fungal biomass as the result of previous fertilizer strategies (Semenov et al., 2022). For nutrient balancing, agronomists assume that the nutrient release of compost is not greater than 20% of its content in the first, and even less in the subsequent years. Thus, the change of management practice from mineral to organic nutrient application, with the sole use of compost, may result in an initial nutrient deficit that is alleviated through repeated additions of compost in the following years.

Microbial diversity, macro and micropores, aggregates and structural stability

Biodiversity is an issue that is attracting increasing attention and so is diversity of soil microorganisms, a subject linked to resilience and resistance toward disturbances (Lynch and St. Clair, 2004). Abundant research has shown that the use of composts contributes to the microbial diversity in soils (Ros et al., 2006; Kurzemann et al., 2020). Microbial diversity benefits soils in two major ways: firstly, by safeguarding a steady nutrient supply through decomposition processes that cope with changing environmental conditions and, secondly, by supplying a microbiota that is disease suppressive. This may work through niche occupation and the generation of substances that are able to hamper the growth of pathogens (e.g., antibiotics produced by actinobacteria). An increased diversity of the microbiota is also the basis for a functioning food web, including protista and other eukaryotes, up to the earthworms. The activity of all these players contributes to the structural stability of soil, ranging from the formation of extracellular polymeric substances (EPS) by biofilm-producing bacteria, the structural network of actinobacterial and fungal mycelia to the secretion of mucilaginous substances by earthworms, strengthening the burrows. The co-occurrence of soil mineral and organic particles and EPS on one hand, and mycelia acting as a fiber-reinforcement on the other, makes resulting aggregates particularly strong.

In this context, the activity of soil fauna becomes important. Compost still contains digestible compounds, earthworms thrive and their burrows, strengthened by mucilaginous compounds, further contribute to the aeration and water conductivity of soils.

Climate related issues

The return of organic materials to soils is a natural way of closing nutrient and carbon cycles. The treatment process may, however, largely determine the climate-compatibility. The composting process releases CO₂, if managed properly. If aeration conditions are not maintained according to best practice, however, creation of considerable methane and nitrous oxide emissions can be a draw-back compared to anaerobic digestion (biomethanization) (Insam and Wett, 2008). Nevertheless, once applied to soil, several aspects contribute to the benefits of compost-based soil management regarding climate.

- Carbon sequestration. Under good process conditions, composting of organic wastes does generate CO₂ but not methane or nitrous oxide gas. The C remaining is in the form of some leftover plant material, (microbial) biomass and humic matter which is recalcitrant and may contribute to the buildup of long-lasting soil organic matter.
- The nutrients returned to soil substitute for chemical fertilizers that require a lot of energy for their production. The production of nitrogen fertilizer alone, based on the Haber-Bosch process consumes up to 2% of the global energy demand.
- Composts improve plant health, and in combination with organic agriculture, use of herbicides and pesticides may be averted.
- Soils amended with composts show an improved structural stability coupled with water retention, resulting in a reduced requirement for watering
- Improved water holding capacity may also help to reduce flooding that appears to become more frequent with climate change.

Conclusion

Nutrient and carbon cycling is a prerequisite for a sustainable economy and particularly concerning agriculture, horticulture and forestry. Bearing in mind the need for climate-friendly action and the need for maintaining healthy soils for the benefit of an increasing world population, composting is a way to get nutrient and carbon flows under control. Appropriately used, composts will render soils as sinks of greenhouse gases and make them less susceptible to erosion, increase their water holding capacity and microbial as well as faunal diversity and maintain their productivity on the long term. Moreover, composts may serve to convert waste lands to productive soils.

Abstract

Landfarming, an aerobic, above-ground, engineered ex-situ bioremediation process, has been used globally since the 1970s for the remediation and restoration of sites impacted by diverse pollutants, principally petroleum hydrocarbons. One of the key actors in removing contaminants during landfarming is the microflora, mainly bacteria and fungi. However, despite the poor understanding of its microbial metabolic features, landfarming technology has become widespread. The present chapter provides an overview of the microbial aspects related to the diversity and composition, biostimulation and bioaugmentation for improving effectiveness, outcomes of recent field-scale studies, efficacy evaluation, and future research directions for the technological advances in landfarming.

Key points

- Bacteria and fungi are the most active degraders of organic contaminants in landfarming
- Bacteria exhibit greater diversity and abundance than fungi at landfarming sites
- Biostimulation and bioaugmentation are the essential landfarm management practices
- Insights into microbial metabolic networks can improve landfarming efficacy
- Continuing research effort is required to ensure the use of landfarming technology for diverse contaminants under extreme environmental conditions

Introduction

'Landfarming' involves natural processes for degrading organic contaminants in excavated soil or sediment *ex-situ*. The contaminated soil or sediment is collected and taken to the land farm, spread, and generally treated on top of the upper soil zone or in a specially designed land-treatment cell. This remediation technology is also referred to as land treatment or land application. The activities of landfarming technology include (i) tilling by agricultural equipment that is easily available, such as chisel plows, rotary tillers, harrows pulled by tractors and (ii) application of mineral or organic fertilizers, pH regulators, and bulking agents that improve structure, texture, aeration, nutrient status and microbial activities of the contaminated soils or sediments. This engineered ex-situ process includes spreading the excavated contaminated soils or sediments as a thin layer above-ground, usually <0.30 m deep, to facilitate tillage operations on a prepared soil surface. These treatment plots are also called 'landfarms.' Landfarms have had

significant success rates in treating the contamination of petroleum hydrocarbon wastes in soils and sediments, drill cuttings, low brine drilling fluids, oily sludges, tank sediments, and pit sludges. These complex mixtures of organic compounds may contain diverse alkanes, aromatics, phenols, paraffins, asphaltenes, and polynuclear aromatic hydrocarbons. Whereas the simple aliphatic and aromatic compounds are easily degradable, other compounds are recalcitrant to microbial degradation. This remediation technology has been used in industrial practice since the 1970s. About one-third of all US refineries in 1983 and nearly 60% of remediation in former military bases in South Korea have included landfarming (API, 2003; Kim et al., 2022). Wider adoption implies recognition of the importance and strengths of physical, chemical, and biological aspects of landfarming technology to degrade the contaminants and restore the contaminated sites. Effective landfarming management depends on the number and diversity of naturally occurring bacterial and fungal populations, which are the critical drivers of biodegradation of contaminants and that can be augmented or stimulated for optimal biotransformation and degradation. Microbial activities that are established during landfarming can degrade specific contaminants in two differentiated phases: the first phase involves the rapid degradation of labile fractions, and the second phase with slower degradation rates due to reduced bioavailability and recalcitrance. Those pollutant hydrocarbons of greater molecular weight, such as polycyclic aromatic hydrocarbons (PAHs), have slower biodegradation rates. But, highly volatile contaminants, such as light petroleum hydrocarbons, are unsuitable because of their high potential for volatilization.

Landfarming under aerobic conditions do not favor the remediation of soils or sediments contaminated with chlorinated and nitrate-containing compounds. The chemical structure, the concentration of the contaminants determines the effectiveness of the degradation processes. At landfarming sites, a biphasic degradation kinetics of contaminants occurs with gradual decreases in microbial respiration rates. The microbial biomass carbon (C), commonly written as C_{mic} , and community diversity indices, such as Shannon H, can decrease along with the microbial respiration rates. Even at small concentrations, contaminants (e.g., total petroleum hydrocarbons (TPHs) of 0.30%) can be toxic to the microbial community. Hence, repeated applications of contaminated soils can may become toxic, rather than acting as substrates for the microbial communities. Other factors that influence the effectiveness of landfarming include soil type and properties, climate and weather conditions at the treatment sites, and the cost involved and volume of the contaminated soil or sediment to be excavated and treated. In landfarms, aerobic microbial activity is stimulated by frequent turnover of the contaminated soil (or sediment) layers by tilling (or plowing) or adding nutrients or moisture. The commonly available tilling equipment limits the depth of contaminated soil to 0.3–0.6 m. Thus, optimization of the landfarming process depends on the soil moisture content, the frequency of aerating practices, and soil pH. Generally, no sophisticated equipment is required, and the standard equipment used for traditional agricultural operations is sufficient to treat the contaminated soil. At the landfarming treatment sites, a protective membrane layer above the natural soil surface of clay or composite liner is preferred when there is a risk of underground water contamination. Using an impermeable membrane such as high-density polyethylene (HDPE) membrane (of 1–10 mm thickness) can prevent groundwater contamination by controlling the leachate movement during landfarming.

Landfarming is thus a low-cost, energy-efficient, and eco-friendly remediation technology for biodegradable contaminants with minimal residue disposal problems. For these reasons, landfarming gained more public acceptance than incineration, landfilling, or deep-well injection. By recycling organic carbon and nutrients from the contaminants within the biosphere, landfarming plays a significant role in maintaining and sustaining soils or sediments critical to supporting healthy ecosystems, including through revegetation and reforestation (Sims and Sims, 2003). Rigorous studies on the bioavailability of pollutants, microbial community dynamics, and the formation of soil-bound residues informing risk assessment and management, are still required to provide valuable insights into understanding chemical-soil-microbe interactions for the risk assessment and management of landfarming technology. The basic scheme of landfarming technology is depicted in Fig. 1.

Fig. 1 A typical set-up of the landfarm technology for contaminated soils or sediments.

Technological importance of landfarming

Landfarming is a cost-effective biological treatment aimed at degrading contaminants by converting them to carbon dioxide and water. Variations in the physical, chemical, and biological parameters of this 'low tech' technology may contribute to or hamper the remediation process. Physicochemical processes such as volatilization, photooxidation, and humification can significantly decrease the contaminant concentration during the initial period. For example, gasoline, a volatile and lighter petroleum product, is removed by volatilization during the aeration process, particularly by tine cultivator or plowing (more intensive tilling) operations at landfarming sites. But the emissions of volatile organic compounds can accentuate air pollution at the landfarming sites. Enclosures such as a greenhouse or a plastic sheet cover will minimize the dissipation of constituent vapors emitted. Capturing and treating the vapors appropriately before venting is another control measure for contaminants with higher volatile constituents. Photooxidation can involve direct photolysis by sunlight and indirect photoreactions by the light-absorbing chromophores. This physicochemical process can oxidize and form new, less-stable reactive intermediate products. However, reactive intermediate products may be more toxic than the parent compounds. In addition, intermediate products are either water-soluble or insoluble polymers. The photo-produced insoluble polymers can form stable and persistent emulsions, making them challenging to degrade during clean-up operations. Humification is a process interconvertible with degradation. Humic substances with $-OH$, $-COOH$, $-CH_3$, $-CH_2$, and $C-H$ groups and aromatic substances can bind organic pollutants; these substances also shuttle electrons for the conversion of organic pollutants in the redox reactions. During the initial period, adsorption of contaminants on soil particles is essential for the dissipation of contaminants. Several mechanisms such as ion exchange, hydrogen bonding, charge transfer, London-van der Waals dispersion forces, and interaction with metallic cations, influence adsorption behavior, especially the bioavailability of contaminants. The significant biological aspect of landfarming is degradation of contaminants mediated by biota. Indigenous microorganisms are critical to biodegradation of contaminants. Both biodegradation and bioavailability determine the cost-effectiveness of landfarming. In some cases, the extent of biodegradation is inversely proportional to increasing contaminant concentrations.

For effectively treating contaminants by landfarming, soil may be used as an inoculum and as a supporting medium for biological growth under aerobic conditions. Factors that can be optimized to maximize remediation are moisture content, oxygen level, nutrients, pH, and soil bulking. Four significant steps in establishing landfarms for treating contaminated soils or sediments, are (i) application of mixing techniques for effective contact ($\sim 90\%$) between soil particles and additives; (ii) addition of inorganic nutrients in the proportion of 100:10:1 hydrocarbon: nitrogen: phosphorous; (iii) mixing the soils with sand, sawdust or wood chips to increase the porosity of the soils; and (iv) adjustment of soil pH by using lime, alum or phosphoric acid. With all these implementations, the typical land-farming cost can be US\$ 50–200 per cubic meter (Cookson, 1995). Nevertheless, the main advantages of landfarming technology are that it is a cost-effective technology, well suited to remote regions, does not require skilled persons, provides optimum conditions for microbial degradation, and has short treatment times (6 months to 2 years maximum) under optimal conditions. On the other hand, landfarming technology has its drawbacks, as it requires ample space, might lead to uncontrolled biodegradation conditions which increases the length of the operation time, is unsuitable for inorganic contaminants, can cause heavy metal toxicity to microorganisms, releases large amounts of particulate matter, may produce leachates, which at vulnerable sites can contaminate groundwater. Above all, the technology is inappropriate for the remediation of sites contaminated with halogenated organic contaminants, creosote, pentachlorophenol (PCP), and bunker C oil, all of which are not degraded by landfarming.

Properties of soil and chemical contaminants and environmental factors

The properties of contaminated soils, the nature of chemical contaminants, and the environmental factors prevalent at the treatment locations significantly affect the microbial activities with consequences for the degradation rates. Successful operation of the landfarming technology necessitates the consideration of those factors related to the soil, contaminants, and the environment (EPA, 2017):

Soil properties

A neutral pH range is optimal (i.e., 6–8) for successful landfarming. The optimal moisture content should be in the range of 40–85% of the water-holding capacity of the soil (field capacity) or 12–30% moisture by weight. Excess moisture should be avoided. Notably, tillage that causes evaporation of soil moisture and high precipitation or poor drainage that results in the excess accumulation of moisture have to be monitored regularly and managed to be in the optimal range for landfarming. Within the 10 °C to 40 °C temperature range, microbial activity doubles for every 10 °C rise; this implies that soil temperature can significantly impact landfarming efficiency. If the soil temperature is cooler than 10 °C, microbial activity substantially decreases; if the temperature goes below 5 °C, the activities of microbes related to contaminant degradation become slow and inefficient. Therefore, the period, when the soil temperature is within the optimal range, is called the 'landfarming season.' In colder regions, psychrophilic bacteria are introduced into the landfarms; these cold-adapted bacteria withstand temperatures cooler than 10 °C and help achieve the goals of landfarming.

The soil texture significantly influences aeration and moisture contents. For example, clay soils compact easily, leading to poor aeration, and have high water holding capacity, retaining water for extended periods following precipitation. Thus, poor aeration and excess moisture content in clay soils may adversely affect the microbial activity at the landfarming sites. Nitrogen and

phosphorus nutrients are added to support microbial cell growth and degradation as these nutrients are usually at insufficient concentrations at the contaminated sites. But, excess nutrients, such as phosphate and sulfate, can repress microbial activities. The concentration ratios of carbon:nitrogen:phosphorus (C:N:P) in contaminated soils or sediments that range from 100:10:1 to 100:1:0.5 are considered favorable for microbial growth. The ratios are decided based on the specific constituents and microbial species that are to be involved in the degradation process. The nutrients to be added are calculated as follows:

Example: The volume of contaminated soils is 90,000 m³, the average pollutant concentration in the contaminated soil is 1000 mg kg⁻¹, and the soil bulk density is 50 kg m⁻³.

Therefore,

$$\begin{aligned}\text{Soil mass} &= \text{Volume of contaminated soil} \times \text{Soil bulk density} \\ &= 90000 \text{ m}^3 \times (50 \text{ kg} \div \text{m}^3) \\ &= 4.5 \times 10^6 \text{ kg}\end{aligned}$$

$$\begin{aligned}\text{Contaminant mass} &= \text{Soil mass} \times \text{Pollutant concentration} \\ &= 4.5 \times 10^6 \times 1,000 \text{ mg kg}^{-1} \\ &= 4.5 \times 10^3 \text{ kg} = 4,500 \text{ kg} (\sim 10,000 \text{ lbs})\end{aligned}$$

For a C:N:P ratio of 100:10:1, 455 kg (or 1000 lbs) nitrogen and 45 kg (or 100 lbs) phosphorus would be required to treat contaminated sites using the landfarming technology.

Contaminant chemical properties

The volatility of chemical contaminants is an essential determinant for microbial degradation. Generally, petroleum hydrocarbon fractions have different proportions of volatile components, which evaporate into the atmosphere during tillage; these compounds are unavailable to microbial degradation. Biodegradation rates depend on the chemical structure of contaminants. The potential microbial degradability of different petroleum hydrocarbons during landfarming is provided in Fig. 2. n-Butane and n-pentane fractions of gasoline are easily degraded by microorganisms but naphthalene, fluoranthene, pyrenes, and acenaphthenes are less degradable.

Concentrations of contaminants

The concentration of contaminants at the sites is also critical to microbial degradation. For example, large concentrations of petroleum hydrocarbons (10,000–50,000 ppm) or heavy metals (>2500 ppm) are toxic and inhibitory to microbial growth. Soils from very contaminated sites may be diluted by adding fresh soil. On the other hand, very low levels of contaminants lead to diminished microbial activity.

Climatic factors

As temperature and moisture are critical to landfarming, the local climatic conditions are crucial. Rainfall determines the success rates of this remediation technology. During and after a significant precipitation episode, the soil moisture content will exceed the requirement for optimum bacterial activity. Drought results in soil moisture becoming below optimum. Both ample precipitation and drought can inhibit microbial activity, thereby extending the period required for successful landfarming.

Fig. 2 Microbial degradability of different petroleum hydrocarbon fractions during landfarming.

Biostimulation

Though microbial activity can increase initially in the contaminated soils without any amendment, a rapid reduction in activity occurs due to a lack of nutrients. The stimulation of the activities of indigenous (autochthonous) contaminant-degrading microorganisms by adding nutrients or substrates to the contaminated soils or sediments is referred to as biostimulation. The adjustment of soil pH, the addition of nutrients (N, P, trace elements), and ensuring optimum moisture content and oxygen concentration are the main levers for the biostimulation of native microflora in contaminated soils or sediments. Biostimulation has been successfully used in landfarming technology to remove and restore PAHs-contaminated soils. Agricultural wastes, such as corn cobs, can be used to overcome nutrient limitations in the landfarming sites. In addition to providing nutrients, using agricultural or industrial wastes or composts can improve the porosity and aeration. Nearly 89% of PAHs were removed in the landfarms where ground rice hulls were added as a bulking agent and dried blood as a slow-release nitrogen source (Nduka et al., 2012). More importantly, the microbial population densities could triple under biostimulation, providing about 90% removal efficiency against <50% in the unamended soils.

Perhaps surprisingly, there is no significant difference between synthetic fertilizer (NPK and urea) and natural organic amendments (e.g., cattle or poultry manure, animal wastes) in stimulating the microbial activity during remediation of soils contaminated with petroleum hydrocarbons. Nevertheless, natural organic fertilizers are preferable as biostimulating agents due to their efficacy and low price. Landfarming of hydrocarbon-contaminated soil in the Niger-Delta (Nigeria) with a combination of nutrients (NPK), biochar and rhamnolipids resulted in the removal of 23% more TPHs than nutrients alone (Brown et al., 2017). Additionally, excess fertilizer application may have a negative impact on nutrient cycling in the landfarms. For example, urea applied at a rate of 893 g N m^{-2} inhibited nitrification at a landfarm site containing 4–6% (w/w) of mineral oil (Peltola et al., 2006). Also, addition of 889 g N m^{-2} methylene urea or 893 g N m^{-2} urea enhanced the removal of mineral oil from the contaminated soil. In another investigation of a 9-month plot-scale landfarm, the nutrient addition (N-P-K + surfactant) stimulated the maximum dehydrogenase activity at the end of 2nd, 4th, and 7th month in soil contaminated with diesel oil (10, 000 and 20,000 mg kg^{-1}) (Fig. 3, Silva-Castro et al., 2015). In a recent report, Johnsen et al. (2021) demonstrated that oil degradation was barely measurable in the absence of added mineral nutrients but greatly increased after their addition, confirming the importance of biostimulation process in activating the local microflora.

Oil spills from meteorological stations, military outposts and research stations occur in the Arctic. Landfarming is an appropriate technology for remediating contaminated soils as the hydrocarbon-degrading microorganisms are commonly prevalent in this region. In a full-scale Arctic landfarm, Johnsen et al. (2021) provided 1636 kg ha^{-1} fast-release fertilizer (total N 15.5%, CaO 26.3%), and 6523 kg ha^{-1} of the NPK fertilizer (total N 12%, total P 4%, K 13%, S 9%, Fe 0.06%, B 0.02%, Zn 0.01%, 3,4-dimethyl pyrazole phosphate as nitrification inhibitor 0.8%) to reach an initial N concentration $\sim 300 \text{ mg kg}^{-1}$ (15% water, wet wt) as amendments while remediating diesel-polluted soils. Finally, there was plowing (30 cm) for aeration and mixing of the soil, and sprinklers were used to release fertilizer from the pellets. This biostimulation method achieved the maximum population of diesel degraders ($1.2 \times 10^9 \text{ cells g}^{-1}$) in that arctic landfarm. Even when the metabolic diversity of the microbial degrader communities is adequate in the landfarms, biostimulation can ensure efficient degradation within a reasonable time frame.

Fig. 3 Dehydrogenase indices in the diesel-polluted soil subjected to a 9-month biostimulation-assisted landfarm site. (C, Natural attenuation; S, Surfactant; NPK (Nitrogen:phosphorous:potassium) at 31:5:7; NPK/S, NPK + surfactant). Based on data from Silva-Castro GA, Uad I, Rodríguez-Calvo A, González-López J, Calvo C (2015) Response of autochthonous microbiota of diesel polluted soils to land-farming treatments. *Environmental Research* 137: 49–58.

Bioaugmentation

Bioaugmentation implies the addition of non-pathogenic contaminant degrading microorganisms to the soil. For successful bioaugmentation, selecting a consortium of autochthonous microflora is preferable for better adaptability to their new environment and increased degradation rates. The microorganisms are usually isolated from soil of the same type as that being remediated to remove any toxicity problem. The bioaugmentation-assisted landfarming shows about 16% and 29% greater efficiencies for removing TPHs than standard landfarming or natural attenuation, respectively (Guarino et al., 2017). In an ex-situ field-scale landfarm, the addition of a commercially available consortium at 1:50 inoculum-soil ratio resulted in the removal of 85% of TPHs after 155 days, with the TPH decay rate of 0.015 day^{-1} against the rate of 0.0069 day^{-1} under the intrinsic conditions (Chien et al., 2010). The survival of the added strains at the contaminated site is one of the significant challenges in bioaugmentation approaches. The competition from indigenous microorganisms and contaminant toxicity are two essential factors that affect the survival and activities of added strains.

Bioaugmentation is often used in combination with biostimulation to achieve better results in the restoration of contaminated sites by landfarming. The application of a consortium of selected bacterial species, combined with inorganic and oleophilic fertilizers can ensure even the efficient removal of PAHs from contaminated soils by landfarming. For example, whereas the biostimulation-based landfarm microcosms had about 34% and 57% removal rates for PAHs, and total BaP, respectively, these values increased to 87% and 67% when biostimulation and bioaugmentation were combined (Straube et al., 2003). The integration of landfarming with the composting of organic wastes can improve the bioremediation performance. In this combined strategy, composting organic waste promotes biostimulation and bioaugmentation, creating favorable conditions for biological activity. Such integrated approaches are economical and effective in removing organic pollutants from contaminated sites.

Microbiological features of landfarming

Large numbers of diverse microorganisms such as bacteria, algae, fungi, and many others, including protists, exist in the soils. However, the most numerous and biochemically active microorganisms in landfarms are bacteria. The activities of specific bacteria and fungi at the contaminated sites for degradation have been identified. For example, the bacteria *Pseudomonas aeruginosa*, *Acinetobacter* spp., *Myroides* spp., and *Bacillus* spp. and fungi belonging to the class *Eurotiomycetes*, *Saccharomycetes*, and *Sordariomycetes* are essential in the degradation of PAHs at spill sites. Many strains of *Alcaligenes* sp., *Enterobacter* sp., and *Ochrobactrum* sp. can degrade several classes of petroleum hydrocarbons.

Bacteriological aspects of landfarming sites

Bacteria are the key microbial degraders of contaminants at landfarming sites. Because of their genetic and metabolic diversity, their ubiquity in terrestrial and aquatic systems, they are naturally abundant at the contaminated sites, Bacteria are responsible for either degradation or mineralization of contaminants at landfarming sites. They act either as individual species or as communities. The preference for different classes of chemical compounds for degradation varies among diverse bacteria. The members of the genera such as *Sphingomonas*, *Sphingobium*, *Novosphingobium*, and *Sphingopyxis* belonging to *Sphingomonadaceae* are efficient degraders of aromatic compounds. For degrading aromatic or aliphatic hydrocarbons, the members of *Xanthobacteraceae* (*Alphaproteobacteria*) and *Pseudomonadaceae* (*Gammaproteobacteria*) have the necessary genes. A species of *Kaistobacter*, belonging to the family *Sphingomonadaceae*, was the most abundant (about 10–60% of the total 16S rRNA sequences reads) in control and the minimally managed oil sludge containing microcosms (Dörr de Quadros et al., 2016). Isolates of this genus are widely distributed in methane-enriched sites, diesel-contaminated soils, and isoprene-contaminated soils. Silva-Castro et al. (2012) identified the changes in the population in terms of the total number of cultural aerobic heterotrophic bacteria over 7 months of landfarming (six different treatments) used for restoring the hydrocarbon-contaminated soil (Fig. 4). Of the six treatments, the one containing a consortium of *Bacillus pumilus*, *Alcaligenes faecalis*, *Micrococcus luteus*, and *Enterobacter* sp. (i.e., treatment D) showed the largest number of culturable heterotrophic aerobic bacteria. In addition, it also removed 90% of PAHs, suggesting the importance of these bacterial species in restoring the contaminated sites by landfarming technology. The bacterial consortium A associated with treatment D was 2.6 times more effective in removing the PAHs than consortium B (associated with treatment E, which only achieved a PAH removal of 34%). However, the provision of NPK to consortium B led to a stimulation of PAH removal efficiency (treatment F, that removed 87% of PAHs). In another landfarming experiment, carried out over 90 days, addition of a bacterial consortium (22 isolates from the hydrocarbon-contaminated site, belonging to the genera *Acetobacter*, *Achromobacter*, *Comamonas*, *Delftia*, *Ochrobactrum*, *Pseudomonas*, *Pseudoxanthomonas*, *Sphingobium*, and *Stenotrophomonas*) improved the efficiency of TPHs removal by 12–80% in 7 out of 8 the landfarming treatments over the control which did not receive the bacterial consortium (Guarino et al., 2017).

The evolutionary relationship of isolated microbial species needs to be compared with the known microorganism degrading specific pollutants to explore the metabolic potentials of microorganisms that can be used in bioremediation. Very recently, two bacterial isolates (*Kocuria flava* DTU-1Y and *Rhodococcus pyridinivorans* DTU-7P) from contaminated soil and have been

Fig. 4 Dynamic changes in the total number of culturable aerobic heterotrophic bacteria and PAHs removal (%) in hydrocarbon-contaminated soil subjected to different landfarming treatments (A, Control; B, amended with NPK fertilizer; C, amended with S200; D, amended with consortium A; E, amended with consortium B; F, amended with NPK fertilizer and consortium A. Consortium A was a mixture of *Bacillus pumilus* 28-11, *Alcaligenes faecalis* 212-2, *Micrococcus luteus* 212-4, and *Enterobacter* sp. 214-6; Consortium B was a mixture of *B. pumilus* 28-11, *Enterobacter* sp. 214-6, and *Ochrobactrum anthropi* AD2). Based on data from Silva-Castro GA, Uad I, González-López J, et al. (2012) Application of selected microbial consortia combined with inorganic and oleophilic fertilizers to recuperate oil-polluted soil using landfarming technology. *Clean Technologies and Environmental Policy* 14: 719–726.

phylogenetically compared with the known PAH-degrading bacteria having PAH-catabolic genes or enzymes and confirmed that strains DTU-1Y and DTU-7P had the potential to utilize PAHs as their sole carbon source for their growth (Sakshi et al., 2020). The microbial activities in the landfarms can be improved by 'surfactant flushing.' Hydrocarbon compounds can easily be removed from the soil through micelle formation and desorption mechanisms using surfactants as a flushing solution. Non-ionic surfactants are widely used in the remediation of soils impacted by hydrocarbon compounds due to their ability to solubilize hydrocarbons. Anaerobic biodegradation is one of the main tasks in cold anoxic regions. The search for novel microbial species that have the potential for oil degradation under anaerobic conditions is of paramount importance. The application of advanced molecular techniques [e.g., metagenomic-Stable Isotope Probing (SIP)] is important in the search for functional microbial species in pristine low-temperature conditions, especially in contaminated sites of Antarctic and Arctic environments. The use of extremozymes and extremophilic organisms is important in the degradation of various pollutants. There is also growing interest in 'nanozymes' to restore contaminated sites (Porto de Souza et al., 2022). Insights into bacterial degraders and their metabolic networks are critical to improving the efficiency of landfarming technology and restoring contaminated sites.

Role of fungi in landfarming sites

Fungi play a considerable role in the degradation of contaminants at the treatment sites with landfarming technology. Since fungi are metabolically diverse, they can degrade a wide range of contaminants such as textile dyes, leather tanning chemicals, petroleum hydrocarbons, PAHs, PPCPs (pharmaceuticals and personal care products), and agrochemicals (such as pesticides and herbicides). Fungal strains have been proven to be an economical, efficient, and environmentally benign agent to restore contaminant sites. The fungal isolate of *Penicillium* sp. 06 from a soil used for landfarming of oily waste degraded about 89% of phenanthrene and more than 75% of acenaphthene, fluorene, and fluoranthene after 30 days of incubation (Zheng and Obbard, 2003). The propensity of *Penicillium* sp. 06 isolate to oxidize high molecular weight PAHs (i.e., chrysene, benzo(a)pyrene, and dibenz(ah)anthracene) was inversely proportional to the molecular weight of the PAHs. *Fusarium oxysporum*, which was isolated from a petrochemical sludge landfarming site, was able to utilize a wide range of organics as its carbon sources, such as pyrene, anthracene, phenanthrene, naphthalene, catechol, gentisic acid, dihydroxybenzoic acid, benzene, ethylbenzene, toluene, xylene, 1-decene, 1-octene, hexane, ethanol, gasoline, and diesel oil (Jacques et al., 2007). The landfarming site for treating oil waste had significant population densities of fungi (total fungi, TF about 2.60×10^5 CFU g⁻¹); fungi are an essential group among microflora associated with the degradation of contaminants, other than heterotrophic aerobic bacteria (HAB) and heterotrophic anaerobic bacteria (HNB) (da Silva et al., 2013). These three microbial groups (TF, HAB, and HNB) were combinedly responsible for reducing TPH content by ~90% at a landfarming site. *F. oxysporum*, isolated from the landfarming site contaminated with PAHs, was one of the potential microorganisms in a mixed consortium of bacteria and fungi prepared for bioaugmentation (Jacques et al., 2008). The mixed consortium was found to degrade anthracene, phenanthrene, and pyrene in the soil over 70 days at removal rates of 99%, 99%, and 96%, respectively. Baron et al. (2021) isolated black fungi (or melanized fungi) from the landfarming site in the oil industry, capable of utilizing toluene as the sole carbon source. These strains were identified as *Cladophialophora minourae*, and *C. immunda*. Tables 1 and 2 provide details of two recent full-scale landfarming studies, one equatorial in Nigeria, the other in Greenland and illustrate the scope and understanding of the latest developments in the microbial features of landfarming technology. At the landfarming site in Niger Delta, 128 bacterial species and 52 fungal species were identified, and 92% of TPHs were removed in 56 days (Table 1). At the arctic landfarming site in Greenland (−10 °C), 64–88% of TPHs degradation was achieved, and the predominant microorganisms were the degraders of undecane, *m*-xylene, 2-methylnaphthalene and phenanthrene (Table 2).

Table 1 Field-scale landfarming of crude oil-impacted soil of the Niger Delta region, Nigeria.

Parameter	Details
Site and study	Landfarming study was carried out in a community in Emohua local government area in Rivers state, Nigeria (E 6.804116; N 4.969581) (Chikere et al., 2019). Duration of study was 56 days.
Microbiological analysis	- Soil samples of 0–2 m depth (from landfarm) were collected to analyze microbiological characteristics - Microbial cultures (bacteria and fungi) were isolated by using crude oil and paraffin wax as enrichment substrates. - Degradative potentials (diesel fuel) of these cultures were analyzed using culture-dependent methods (2,6-dichlorophenol indophenol (DCPIP) decolorization test). - Further hydrocarbon degradation potentials were tested using 96-well microtiter plate, and degradation potentials were monitored using Varioskan Flash Plate Reader for 0–144 h
Genomic analysis	- Soil genomic DNA (using Zymo Research fungal/bacterial DNA MiniPrep kit) was analyzed in this study. - Both bacterial and fungal sequences were subjected to phylogenetic analysis
Findings	- One hundred and twenty-eight bacterial and 52 fungal species were isolated in this study by enrichment techniques (crude oil and paraffin wax substrates). - In DCPIP decolorization test, 31 out of 128 isolates have shown decolorized diesel completely within 24 h, while 16 out of 31 strains have hydrocarbon degradation potential. - Crude oil and paraffin wax encouraged the growth of hydrocarbon utilizing bacteria (HUB) by 99.97% and 80.36%, respectively. - Both bacteria (of Proteobacteria and Firmicutes) and fungi (of Eurotiomycetes, Sordariomycetes, and Saccharomycetes) were recovered from the landfarming soil. - Maximum counts of culturable heterotrophic bacteria (CHB) and HUB were 6.80×10^7 (achieved on 18 and 36 day) and 6.80×10^7 (on day 36), respectively and their corresponding 0-day counterparts were 0.20×10^3 and 0.50×10^3, respectively. - TPHs concentration in landfarm was decreased from 8635.68 to 677.2 mg kg⁻¹ in 56 days

Table 2 Landfarming of diesel-polluted soil in Arctic region, Greenland.

Parameter	Details
Site and study	- This landfarming study was carried out at 9117 Mestersvig, sandy river delta (UTM zone 27: 400500 E; 8717500 N) in Greenland (Johnsen et al., 2021). It is an arctic climate with a yearly mean temperature and precipitation of -10°C and 300 mm year⁻¹, respectively. - Approximately 3000 m³ contaminated soil was distributed in an area of 8500 m² with 0.4 m thick layer in landfarm of 13,600 m² (160 × 85 m). - Fast release N-fertilizer (1636 kg ha⁻¹) and NPK (6523 kg ha⁻¹) were added to landfarms as a part of biostimulation
Microbiological analysis	Samples were most probable number (MPN)-enumerated for degraders that could grow on different hydrocarbons, i.e., arctic grade C diesel (10%, v/v), undecane (10%, v/v), <i>m</i>-xylene (15, v/v), 2-methylnaphthalene (2%, w/v), phenanthrene (saturated solution), biphenyl (25%, w/v), benzothiophene (0.50%, w/v), cyclodecane (10%, v/v), 1,3-dimethylcyclohexane (10%, v/v), <i>n</i>-butylbenzene (1%, v/v), sec-butylbenzene (1%, v/v), 1-hydroxynaphthalene (0.50%, w/v), or 1-naphthoic acid (0.50%, w/v) as single carbon sources.
Findings	- TPHs were removed by 64% in the first year (2012–13) and a total of 88% TPHs were removed by the end of landfarming (2012–17). - MPN of Arctic diesel degraders was changed from 1.30×10^6 to 1.20×10^9 cells g⁻¹ between 2012 and 2015 which was corresponded to 40% removal of TPHs during the above period. - There was a decline in MPN of diesel degraders from 1.20×10^9 to 1.10×10^8 cells g⁻¹ between 2015 and 2017, probably TPHs were already degraded by that period. - Higher log (MPN) (i.e., >6–10) in degraders of undecane, <i>m</i>-xylene, 2-methylnaphthalene and phenanthrene was found in three landfarms compared to log (MPN) of ~5 to 1 in background soil samples, in situ remediated soil, basin 1 water, basin 1 sediment, basin 2 water, and basin 2 sediment. - MPN counts for different hydrocarbons were as follows: diesel (<800 cells g⁻¹), cyclodecane (<800 cells g⁻¹), <i>n</i>-alkane (5.50×10^8 cells g⁻¹), <i>n</i>-butylbenzene (2.40×10^6 cells g⁻¹), sec-butylbenzene (1.50×10^8 cells g⁻¹), <i>m</i>-xylene (3.0×10^7 cells g⁻¹) and 1-hydroxynaphthalene (<800 cells g⁻¹). - MPNs were also detected for phenanthrenes, 1-methylnaphthalene, and 2-methylnaphthalene. Detection of MPNs for later two compounds indicate the microbial degradation of C1–naphthalene. - Cultivable benzothiophene MPNs were not detected, which implied that there was no biodegradation of benzothiophenes and dibenzothiophenes. - The ratio of 2MN/1MN (MN, methylnaphthalene) dropped to 84% in the landfarm in 2012, suggesting that biodegradation of naphthalenes had already started by the time of excavation and landfarm construction. In 2013, 2MN/1MN ratio in the landfarm was dropped further to 37%, indicating that there was high C1–naphthalene biodegradation. In the following period (i.e., 2014–17), 2MN/1MN ratio was almost constant which implied that C1–naphthalenes were almost completely removed by 2013. - Regarding alkane degradation, the ratios of nC17/Pr (Pr, Phenanthrene) and nC18/Pr were found to be 17% and 18%, respectively until 2016 landfarming, which suggested that there was continuous degradation of <i>n</i>-alkanes, and this was corroborated with the very high number of undecane degraders in the landfarm soils

Molecular microbial diversity and abundance

The microbial capabilities to degrade the contaminants have relied on the knowledge gained from the cultivated microorganisms before the introduction of molecular methods. The nucleic acid-based techniques such as electrophoresis-based fingerprinting, sequencing, metagenomics, and other omics-based analyses demonstrate the enormous taxonomic- and metabolic diversity of microorganisms involved in the degradation of contaminants at the landfarming sites. Metagenomics show the diversity and abundance of several microorganisms and their metabolic networks at the landfarming sites (Bergsveinson et al., 2019; Kim et al., 2021). In a study on landfarming of TPH-contaminated soil, the operational taxonomic units (OTUs), Chao1 richness index, and Shannon diversity index were found to decrease at the TPHs-contaminated site, relative to the control site, after the landfarming treatment (Kim et al., 2021). The respective values of OTUs, Chao 1 and Shannon indices for the landfarm site were 815 ± 111 , 1000 ± 101 , 7.06 ± 0.29 , while those for the control site were 1265 ± 308 , 1475 ± 340 , and 8.58 ± 0.62 . During the degradation of TPHs, there were increases in the relative abundance (%) of *Proteobacteria* and *Acidobacteria* at the landfarming site compared to the control site (Fig. 5). Nevertheless, other bacterial phyla (notably *Actinobacteria*, *Firmicutes*, *Chloroflexi*, *Gemmatimonadetes*, and *Bacteroidetes*) decreased at the landfarm site over the control site (Kim et al., 2021). Biochemically, there were enhanced microbial respiration rates, soil contents of microbial biomass-nitrogen, and increased urease activities (about 21–45% in 1–4 months) at the PAHs-contaminated landfarming sites over the control sites (Besalatpour et al., 2011).

The success of the landfarming used to restore the long-term contaminated soil can be assessed by novel approaches, such as the identification of prokaryotic communities using combined profiling of both rRNA genes and rRNA. This approach allows us to investigate pollution-dependent differences at a molecular level (i.e., 16S rRNA and rRNA gene pools). The investigations on how different biogeochemical cycling processes mediated by bacteria are affected at the landfarms show the significance of nitrogen cycling microbial communities on contaminant degradation. The abundance of ammonia-oxidizing bacteria (AOB) in the landfarming soil containing high concentrations of oil hydrocarbons ($10,000\text{--}15,000 \mu\text{g g}^{-1}$) and PAHs ($172\text{--}305 \mu\text{g g}^{-1}$) were in the range of 4×10^5 and 9×10^5 cells g^{-1} dwt soil, respectively (Kurola et al., 2005). Further phylogenetic analysis revealed that out of a total of 10 different AOB-like sequences recovered, six sequences were grouped with *Nitrospira* cluster 2 and four with *Nitrospira* cluster 3, suggesting that there were no major temporal changes in the AOB community composition during the studied period of landfarming (Kurola et al., 2005). Oil sludge containing microcosms treated by the landfarming technique was found to have the following predominant bacterial families: *Comamonadaceae*, *Ectothiorhodospiraceae*, *Pseudomonadaceae*, *Sphingomonadaceae*, *Xanthobacteraceae*, and *Xanthomonadaceae* (Dörr de Quadros et al., 2016). Soil amendments significantly impact the microbial community structure at the landfarming sites, which can be discerned by applying molecular methods. The addition of sludge, compost, nutrients, fern, or even the TPH-degrading bacteria to the diesel- and lubricant oil-contaminated soils treated by the enhanced landfarming technique resulted in an increased abundance of microbial species, with slight changes in the dominant species (Wang et al., 2016). However, molecular methods have made the identification of individual microbial species easier, which is otherwise difficult by the cultivation-based methods. In the same study, 34 specific TPH-degrading bacteria have been identified in the microcosm soils—these bacteria include *Acinetobacter* sp., *Acidovarax* sp., *Aquabacterium* sp., *Aquicola tertiarycarbonis*, *Azoarcus* sp., *Bordetella* sp., *Burkholderia* sp., *Caldimonas* sp., *Chlamydia* sp., *Chloroflexi* sp., *Eubacterium* sp., *Ideonella* sp., *Lautropia* sp., *Leptothrix* sp., *Leptothrix ginsengisoli*, *Limnohabitans* sp., *Methyloversatilis* sp., *Microbacterium* sp., *Pseudomonas aeruginosa*, *Pseudomonas* sp.,

Fig. 5 Relative abundance (%) of bacteria at phylum level in a total petroleum hydrocarbon (TPH)-contaminated soil after landfarming (LF). Source: Kim J-W, Hong Y-K, Kim H-S, et al. (2021) Metagenomic analysis for evaluating change in bacterial diversity in TPH-contaminated soil after soil remediation. *Toxics* 9: 319.

Pseudoxanthomonas sp., *Ralstonia* sp., *Rhodoferrax* sp., *Thiothrix* sp., *Variovorax* sp., *Verrucomicrobium* sp., and *Zoogloea* sp. Recently, the impact of soil conditions on microbial communities in a landfarm for hydrocarbon waste (Regina, Canada) was investigated through the analysis of bacterial and fungal community structures using the next-generation sequencing (NGS) techniques (Bergsveinson et al., 2019). While the diversity and structure of bacterial communities were stable, the fungal community structure was less stable due to the influences of the variable soil oxygen conditions. In the landfarm metagenomics identified ~1200 and ~400 OTUs bacteria and fungi, respectively, belonging to 23 bacterial and seven fungal phyla. Bacterial diversity was significantly greater in the surface soil with different landfarming sections or depths than the fungal diversity.

Evaluation of landfarming efficacy

The effectiveness of landfarming technology is evaluated based on three significant components: soil, contaminants, and climatic conditions. The soil characteristics are assessed for many parameters, including the population densities of microbial degraders, pH, moisture content, temperature, nutrient concentrations, and soil texture (Fig. 6). The volatility, chemical structure, concentration, and toxicity are the essential chemical parameters considered for the contaminants (Fig. 7). The key elements of climate, such as ambient temperature, rainfall, and wind, are also appraised.

The microbial activities necessitate an evaluation of the type and degree of contaminants. The assessment helps to exclude the substances that might be toxic to certain microbial species at the site. Under the following conditions the contaminated site is usually considered hazardous and landfarming technology is not feasible due to toxicities to soil microorganisms (FCSAP, 2013).

- TPHs or total extractable hydrocarbons (TEHs) are >3%
- Total heavy metal concentration is >2500 ppm
- Electrical conductivity is >4 dS m⁻¹
- The sodium adsorption ratio (SAR) is >6

For effective landfarming, the population densities and dynamics of contaminant-degrading microbial communities are paramount. The preferred minimum heterotrophic plate count for effective landfarming is 10³ CFU g⁻¹ (Fig. 6). If the microbial population density is below the minimum value, landfarming can still be effective if one of the following two approaches is adopted—(i) stimulating existing bacteria by adding nutrients and (ii) soil amendments to increase the bacterial population. The addition of non-indigenous microflora to the contaminated sites has generally had limited success (FCSAP, 2013). It is always preferable to activate the indigenous microorganisms for achieving effective landfarming. Though commercially available microbial cultures are also popular, the cold-adapted native microorganisms for the arctic and sub-arctic regions are not readily available in landfarming technology.

Biotreatability studies are beneficial in determining the suitability of landfarming technology. Examining gas chromatography (GC) data is useful in pre-assessment of landfarming efficiency. The GC data improve understanding the influence of the chemical composition of a pollutant on landfarming efficacy. It is significant in deciding the site-specific suitability and estimating the necessity of other remedial approaches for the landfarming technology. The biotreatability studies determine how readily treatable are the contaminants or wastes present, and establish the disappearance, over time, of wastes due to the activities of either indigenous or exogenously added microorganisms. The chemical, physical and biological conditions are all considered during the biotreatability studies. Overall, treatability studies are set to determine the following parameters:

- Biodegradability of key chemical(s)
- Rate of O₂ consumption or CO₂ generation as an indicator of biological activity
- Rate of chemical substance(s) degradation, and
- The need for microbial species with degradation efficiencies and determine the effects of microorganisms on degradation rates.

The negative impacts (i.e., terrestrial ecotoxicity, aquatic ecotoxicity, and aquatic eutrophication) of landfarming can be evaluated by an appropriate life cycle assessment (LCA). The LCA of landfarming technology can help to treat the contaminated site in an effective eco-friendly manner. Evaluation of LCA at a landfarming site, using software such as SigmaPro 9.0™, makes it easy to identify environmental hotspots and to reduce the ecological impact.

Summary

Landfarming is an established ex-situ bioremediation technology, and has received wide public acceptance owing to its suitability for the remediation of different contaminant types, the biodegradation potential, the facility design and operation, and the clean-up levels that can be achieved. This bioremediation technology has successfully restored soils contaminated by kerosene, diesel, jet fuel, crude oil, oil-based drilling wastes, oily sludge, tank bottoms, and pit sludges. The susceptibility of contaminants to microbial attack during landfarming is greatly influenced by their molecular structure, chemical properties, and the mixture effects. The key factors for effective landfarming include, but are not limited to, the initial concentration of contaminants, soil pH, aeration or tillage, and

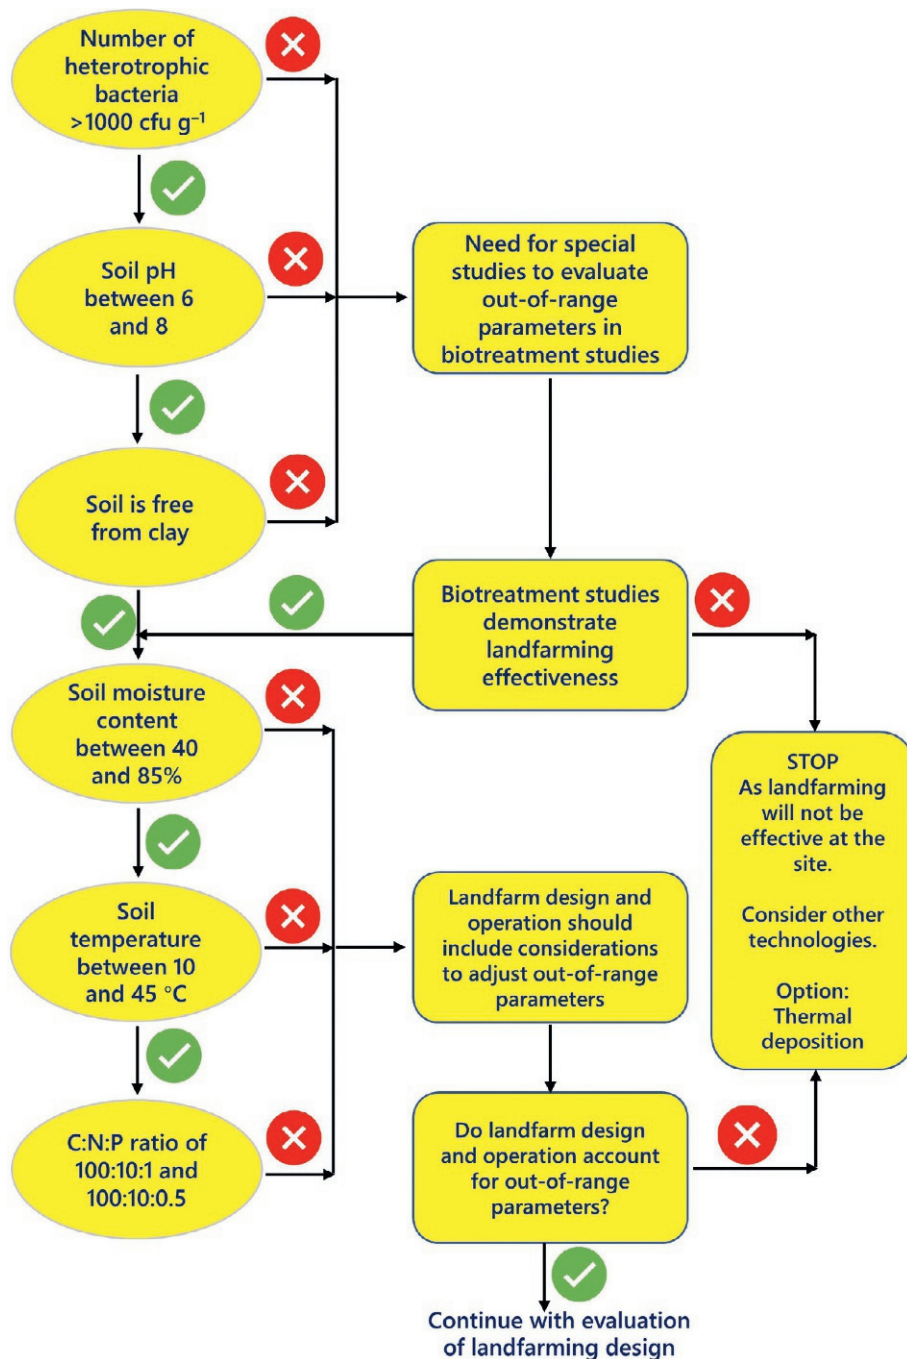

Fig. 6 Analysis of soil characteristics in the evaluation of landfarm efficacy. United States Environmental Protection Agency—October 2017.

the contents of salt and nutrients. The new insights related to biostimulation, bioaugmentation, and the diversity and metabolic activities of microorganisms can help further improve the landfarming technology's applicability to various contaminated sites.

It may thus be concluded that:

- the success of landfarming technology is considerably impacted by pH, moisture content, temperature, nutrient concentration, and texture of the soil, the chemical structure, concentration, volatility, and toxicity of contaminants, and the ambient temperature and rainfall at treatment sites.
- this ex-situ bioremediation technology in combination with biostimulation and bioaugmentation management strategies can effectively restore contaminated sites.

- bacteria and fungi are the primary active microbial groups at treatment sites; the richness and abundance of these microbial groups are greatly influenced by the management practices that are adapted at the treatment site and the nature of the contaminant.
- field-scale studies provide the scope and useful insights into understanding the substantial role and the microbial potential for contaminant degradation in landfarming technology.

Further insights into microbial degradation potential and their metabolic networks are required if we are to make landfarming more effective and more eco-friendly. Knowledge from future investigations may help to overcome the constraints and limitations of

landfarming technology related to moisture, temperature, pollutant bioavailability, nutrient availability, and aeration. Focusing on advanced molecular approaches, enzyme engineering, omics-based approaches, and other emerging techniques will provide even better tools for effectively applying diverse microbial groups at the landfarming sites. Such approaches can help identify the suitability of a microbial species or community for a specific pollutant. The new advances and a better understanding of microbial dynamics and networking will help optimize the environmental conditions for enhanced biodegradation activities during landfarming. Landfarming technology that employs the passive treatment with minimal costs and energy is very promising for the remediation of hydrocarbon-, PAH- and mineral oil-contaminated soils or sediments. The knowledge and information on when, and to what extent, the method can be optimized to improve microbial activities, the bioavailability of the contaminants, and the aerobic conditions are critical to popularize and apply this technology to other contaminants. Regular monitoring of microbial degradation efficiencies can provide the decision support on the efficacy of landfarming technology and tracking when regulatory targets are attained during the remediation of contaminants.

Abstract

Perhaps the most important parameter determining the fate of an organic contaminant in soil is its susceptibility to biological degradation. This article summarizes current knowledge on chemical biodegradation, including microbial mechanisms, chemical and environmental factors that govern rates and extents of biodegradation in soils, and likely impacts of climate change on this process.

Key points

- Microorganisms biodegrade most organic chemicals.
- Aerobic and anaerobic transformation processes occur.
- Numerous chemical and environmental factors affect rates of contaminant biodegradation.
- Climate change is likely to impact biodegradation processes in many ways.

Introduction

Industrialized societies annually release large quantities of synthetic chemicals into Earth's natural environments, both intentionally, in the case of pesticides, and inadvertently, through the production, transport, refining, and combustion of fossil fuels, waste streams from manufacturing, chemical spills, disposal of products by consumers, and discharges from a wide variety of other sources. Currently, there are more than 86 000 chemicals registered in the US Environmental Protection Agency (US EPA) inventory of chemical substances manufactured or processed in, or imported into, the United States (USEPA, 2021). The number of potential chemical pollutants is substantially higher, as the EPA inventory does not include pesticides, radioactive materials, food additives, drugs, or cosmetics. Many of these compounds ultimately end up as contaminants in the atmosphere, water, sediment, or soil. To add to the complexity of the problem, the compounds of concern vary widely in their characteristics. A contaminant can belong to any of a number of disparate classes of compounds that differ in important properties such as charge, polarity, water solubility, acid dissociation constant (pK_a), molecular weight, and aromaticity. These chemical characteristics subsequently determine the fate of a contaminant in the environment and the hazard it poses to humans and other organisms.

Perhaps the most important parameter determining the fate of a given chemical is its susceptibility to biological degradation. There have been more than seven decades of research into chemical biodegradation, including microbial mechanisms and the chemical and environmental factors that govern its rate and extent in soils.

Biodegradation

Biodegradation is the partial or complete breakdown of a chemical pollutant resulting from the physiological reactions of microorganisms. In general, microorganisms carry out such processes to obtain necessary carbon, nutrients, and energy for their survival and growth. Through the millennia, bacteria have experienced extreme competition (primarily from each other) for limiting resources. As a result, they have evolved unrivaled metabolic capabilities, utilizing nearly every thermodynamically favorable reaction for energy and nearly every organic molecule for carbon. For example, whereas humans gain energy only through the oxidation of specific organic substrates using oxygen as an electron acceptor (i.e., through aerobic respiration), bacteria utilize virtually all natural and many man-made organics, numerous inorganic molecules (e.g., Fe(0); Fe(II), H₂S, S(0) H₂, NH₄⁺), and light for energy (Madigan et al., 2018). Moreover, besides oxygen, specific microorganisms can utilize a variety of chemicals, including an assortment of synthetic pollutants and pesticides, as terminal electron acceptors. Specific examples of microbial biodegradation processes under aerobic and anaerobic conditions are provided in subsequent sections.

The microbial degradation of contaminants can yield many different products. Generally, the biodegradation of a large organic molecule results in smaller, less complex organic molecules that may be more or less toxic than the parent compound. In some cases, an organic contaminant is completely converted to an inorganic product such as CO₂. A transformation of this type is referred to as “mineralization” and is associated with the elimination of toxicity of the parent compound. Although plants, animals, and microorganisms can all metabolize some pollutants, the mineralization of organic contaminants is generally carried out by bacteria, fungi and archaea only. These three groups of microorganisms are responsible for nearly all the relevant biotransformations of environmental contaminants.

Whereas biodegradation occurs naturally in soils and other environments without any intervention, bioremediation involves the application of natural processes to remove pollutants from contaminated sites (Alexander, 1999). In short, bioremediation is the use of microorganisms to clean up unwanted compounds, although the specific technology employed will depend on the nature of the site and the contaminant-of-concern. Contaminants may be treated *in situ* through the addition of nutrients to stimulate indigenous microorganisms (biostimulation) or by the inoculation of specific microorganisms capable of degrading the compound (bioaugmentation). Alternatively, contaminated soils can be excavated and treated *ex situ* using biological reactors, composting, or other approaches.

The biodegradation of soil pollutants is critical because of the impact the resultant transformations can have on human and environmental health. For example, in the absence of appreciable degradation, compounds released into soil may leach to groundwater. Contamination of groundwater poses a serious threat to drinking water supplies and public health. Moreover, compounds present in groundwater tend to persist much longer than those in soils due to the limited supplies of oxygen and inorganic nutrients and low microbial numbers generally found in subsurface aquifers. Soil pollutants and pesticides can also pose a threat to human and nonhuman health if they are bioconcentrated by soil organisms. Biological uptake directly from soil can adversely affect both individual organisms and food webs. A contaminant may be sufficiently concentrated in soil to harm the organism that contacts it initially. However, certain compounds, even if originally present at low concentration, can be accumulated and magnified through herbivory and predation. A biomagnified compound has the potential to damage organisms at higher trophic levels, despite their very limited contact with the contaminated soil. Alternatively, some compounds are so potent that they are a threat at very low concentrations. Microbial transformations can lower the risk associated with a particular contaminant because they reduce or eliminate the toxicity of the compound.

Aerobic transformation processes

Many different synthetic organic pollutants and pesticides have been shown to serve as growth substrates for specific bacteria and fungi under aerobic conditions, providing both carbon and energy to these organisms. Often, these compounds are completely mineralized by one organism or by a series of different organisms to CO₂ and cell constituents. During this process, the novel pollutant is generally modified by specific enzymes to one or more metabolites that are common in cellular metabolism (e.g., pyruvic acid, acetyl-CoA). Those metabolites are then converted to energy and biomass through the common metabolic pathways. Aerobic mineralization is typically a growth-linked process whereby microbial numbers increase as the chemical concentration decreases. Growth-linked biodegradation is desirable in that it can bring about a rapid loss of a pollutant from soil. Many different organic contaminants are subject to mineralization in soils, including most components of crude oil and gasoline, and numerous pesticides.

A variety of organic chemicals are biotransformed through a non-growth-linked process termed “cometabolism.” Cometabolism is the fortuitous transformation of a molecule by an enzyme synthesized within a cell for another purpose. By this process, the cell modifies the chemical structure, but gains no energy, carbon, or inorganic nutrients from the reaction. Several groups of aerobic bacteria present in soils, including methanotrophic bacteria (which oxidize methane for energy), nitrifying bacteria (which oxidize ammonia for energy), and ethane- propane-, isobutane-, benzene-, phenol-, and toluene-oxidizing bacteria, have been observed to transform a variety of different compounds through cometabolic reactions. Each of the above groups of bacteria produces nonselective monooxygenase or dioxygenase enzymes that are responsible for these reactions. For example, methanotrophic

Fig. 1 Representation of an individual methanotrophic bacterium degrading methane to carbon dioxide through growth-linked metabolism and degrading trichloroethylene (TCE) to TCE-epoxide via cometabolism. MMO, methane monooxygenase.

bacteria produce methane monooxygenase (MMO), an enzyme that normally functions to oxidize methane for energy (Fig. 1). However, MMO has a broad substrate specificity and has been observed to catalyze the initial oxidation of numerous alkanes, alkenes, and aromatics as well as the degradation of an array of chlorinated aliphatics, such as *cis*- and *trans*-1,2-dichloroethylene (*cis*- and *trans*-1,2-DCE), trichloroethylene (TCE), and 1,2-dichloropropane (Frascari et al., 2015). As previously noted, bacteria do not gain carbon or energy from the cometabolic oxidation of most compounds; thus, an additional cosubstrate is often required for bacterial growth (e.g., toluene for toluene oxidizers, methane for methanotrophs, etc.). Although cometabolic reactions sometimes result in the accumulation of persistent intermediates, in many instances, the initial oxidative reaction produces readily degradable compounds that are then mineralized. For example, as shown in Fig. 1, the initial cometabolic attack of MMO on TCE creates an unstable TCE-epoxide, which further degrades to a variety of growth substrates, such as glyoxylate, formate, and dichloroacetate.

Most recently, cometabolic biodegradation research has focused on a wide variety of emerging contaminants, including methyl *tert*-butyl ether (fuel oxygenate), 1,4-dioxane (stabilizer in chlorinated solvents), *n*-nitrosodimethylamine (disinfection and liquid rocket fuel byproduct), 1,2-dibromoethane (soil fumigant and scavenger in leaded fuels), 1,2,3-trichloropropane (solvent and pesticide manufacturing byproduct), and a broad assortment of trace-level pharmaceuticals, antibiotics, estrogens, and personal care products detected in wastewater treatment plant sludges that may ultimately end up in soils (e.g., Fischer and Majewsky, 2014). Often, these compounds are present in the environment at concentrations too low to support microbial growth, but higher than relevant regulatory or toxicity thresholds. Because microbial growth is dependent on a secondary substrate (e.g., propane or methane) during cometabolism rather than the contaminant-of-concern, the process often can be used as a bioremediation strategy to effectively treat the aforementioned contaminants to very low concentrations (e.g., ng/L in water). This cometabolic bioremediation process typically entails adding a gaseous growth substrate, one of more inorganic nutrients (e.g., ammonia), and oxygen to the impacted environment to stimulate indigenous bacteria capable of carrying out the cometabolic transformations.

Anaerobic transformation processes

A wide variety of contaminants and pesticides are subject to biodegradation under anaerobic conditions. As described for aerobic degradation, mineralization and cometabolic reactions also occur in anaerobic environments. For some compounds, biodegradation will only occur under such conditions, since the organisms capable of carrying out the process are obligate anaerobes (i.e., they die in the presence of oxygen). Under anaerobic conditions, the degradation of specific pollutants and pesticides can be coupled to the reduction of terminal electron acceptors other than O_2 , such as NO_3^- , Mn(IV) , Fe(III) , SO_4^{2-} , or CO_2 . This process is termed "anaerobic respiration." The gasoline constituent toluene, for example, has been reported to be biologically degraded with each of these different electron acceptors. For a given substrate, the energy yield during anaerobic respiration is less than for the same reactions using oxygen ($\text{O}_2 > \text{NO}_3^- > \text{Mn(IV)} > \text{Fe(III)} > \text{SO}_4^{2-} > \text{CO}_2$) as an electron acceptor (Madigan et al., 2018). Therefore, the anaerobic reactions tend to occur more slowly, and microbial growth yields are lower than for aerobic reactions.

If a large quantity of a readily biodegradable organic pollutant is added to a soil, it is not uncommon for the dominant, terminal electron-accepting reaction to progress from aerobic respiration (with O_2 as the primary electron acceptor) all the way to methanogenesis (with CO_2 as the primary acceptor), passing through each dominant electron acceptor in the order shown in Fig. 2. Some microorganisms (e.g., facultative anaerobes) can utilize more than one electron acceptor, although rarely are these reactions performed simultaneously by a given organism. For example, many denitrifying bacteria grow aerobically in the presence of oxygen, then anaerobically on nitrate when oxygen levels are reduced. Other microorganisms, including many sulfate-reducing bacteria, are obligate anaerobes and are capable of using only one of the common electron acceptors (i.e., sulfate) for growth. As electron acceptors are depleted in sequence, the dominant metabolic reactions (and in many instances, the dominant microorganisms) accounting for the chemical losses shift. The reduction potential declines accordingly as the sequence of terminal electron

Fig. 2 Sequence of common electron-accepting reactions. Reactions are given in general order of occurrence from top to bottom, with the reactions at the top taking place at the highest redox potential and providing the highest energy yield to microorganisms during degradation of a given organic compound.

acceptors progresses from oxygen to carbon dioxide. In the absence of available external electron acceptors, some organic molecules are also subject to fermentation, whereby small amounts of energy are gained by an organism through internal oxidation-reduction reactions. However, when all common electron acceptors are consumed in a contaminated soil, the biodegradation reaction is likely to cease, even though biodegradable compounds are still present. It is for this reason that oxygen is frequently added via sparging or other means to enhance biodegradation in environments that have experienced heavy contamination with organic pollutants. It may also be necessary to add inorganic fertilizers in such instances, as the supply of macro- and micronutrients in the soil may be inadequate to sustain microbial degradative activity.

Some groups of chlorinated pollutants, including polychlorinated biphenyls (PCBs), chlorophenols, chlorinated solvents, and certain organochlorine pesticides can serve as alternate electron acceptors, by a process known as reductive dechlorination (also called dehalorespiration) (Fincker and Spormann, 2017). This process, which occurs only in the absence of oxygen, is a critical step in the degradation of these persistent pollutants. During reductive dechlorination, bacteria transfer electrons from a growth substrate (primarily hydrogen) to the chlorinated compounds, causing the release of chloride ion and the production of various organic daughter products. For example, during reductive dechlorination of perchloroethylene (PCE), the daughter products are TCE, *cis*-1,2-DCE, vinyl chloride (VC), and ethylene, respectively (Fig. 3). The occurrence of these degradation products (particularly *cis*-1,2-DCE and VC) suggests that reductive dechlorination of PCE or TCE is occurring in an anaerobic environment. A similar reaction has been noted for PCBs and several organochlorine pesticides (e.g., 1,1,1-trichloro-2,2-bis (4-chlorophenyl)ethane (DDT); pentachlorophenol (PCP); and 3,5,6-trichloro-4-amino-2-pyridinecarboxylic acid (picloram)) under strongly reducing conditions. In soils, reductive dechlorination of PCBs is observed as a shift in the representative PCB congeners found within an environment (there are 209 PCB congeners based on possible positions and numbers of chlorine atoms on the biphenyl molecule) from more chlorinated to less chlorinated congeners. Other chemical pollutants such as perchlorate (ClO_4^- ; an oxidant used in solid rocket fuel) and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX; an explosive), have also been observed to serve as terminal electron acceptors in soils.

Chemical properties affecting biodegradation

All natural organic compounds are biodegradable. The occurrence and rates of biodegradation of these compounds vary widely depending on environmental conditions and chemical complexity (e.g., lignin biodegradation is extremely slow, even under ideal conditions), but it is generally believed that no natural organic materials are completely resistant to microbial destruction. Given hundreds of millions of years of evolution and the constant competition among microorganisms for limiting nutrients and energy, it is not surprising that microbial enzymes have naturally coevolved in step with new organic compounds. In contrast to nature, however, rapid advances in organic chemistry have allowed mankind to develop and produce an overwhelming array of new organic compounds in a short time period. A majority of these thousands of new compounds have been introduced to the Earth's

environment for the first time since the mid-1940s. Many of these chemicals, particularly those that are similar in structure to naturally occurring organics, have proven to be readily biodegradable. Other, more novel synthetics, however, are highly resistant to microbial attack.

Some of the key factors that influence the degradability of a molecule include the type, number, and location of molecular substituents, the type of bonds, the degree of branching, and the molecular weight of the compound (Fig. 4) (Alexander, 1999). The addition of new organic or inorganic substituents to a common molecular structure is one means of creating novel synthetic compounds. Small differences in the type and location of these substituents can determine whether a molecule is readily biodegradable or highly persistent. Contaminants that are resistant to biodegradation owing to their chemical structure are termed “recalcitrant” molecules. A number of synthetic organic compounds and pesticides have been developed by adding halogens (particularly chlorine, fluorine, and bromine) to organic compounds. Because the halogen-carbon bond is very stable and resistant to microbial attack, this type of substitution tends to make a molecule recalcitrant, with increasing halogenation leading to increasing persistence. For example, organochlorine pesticides, such as DDT, toxaphene, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), pentachlorophenol, chlordane, aldrin, hexachlor, and methoxychlor, were once widely used. Many of these pesticides have now been banned from use in the United States and most European countries due to their long-term persistence and negative impacts in various ecosystems. These molecules proved to be highly resistant to aerobic biodegradation and persistent or very slowly degraded under anaerobic conditions. Halogenated pollutants such as PCBs, polybrominated biphenyls (PBBs), freon propellants and refrigerants (e.g., CCl_3F , CCl_2F_2), and chlorinated solvents (e.g., PCE, carbon tetrachloride) have also proven to be persistent contaminants.

In recent years, there has been growing concern over the long-term persistence and toxicity of per- and polyfluoroalkyl substances (PFAS), which represent a broad family of highly fluorinated molecules that have been used in many different products, including fire-fighting foams, stain-resistant fabrics, non-stick cookware, food packaging, electronics manufacture and electroplating, as well as numerous consumer products (Kwiatkowski et al., 2020). PFAS include more than 5000 different chemicals, the most commonly studied of which are perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS). The widespread use of aqueous film forming foam (AFFF) in fire training and firefighting has led to the most significant soil and groundwater contamination with PFAS, some of which are considered a risk at ng/L or ng/kg concentrations in environmental media. PFAS are extremely recalcitrant to mineralization and have been sometimes termed “forever chemicals”, because many have a fully or nearly fully fluorinated C_4 to C_{14} carbon backbone that is highly resistant to enzymatic attack. That being said, recent studies suggest that an

anaerobic iron-reducing bacterium (*Acidimicrobium* strain A6), which typically grows under acidic conditions using ammonium as an electron donor, is capable of substantially defluorinating some PFAS and cleaving the carbon backbone (Huang and Jaffe, 2019). In that the organism does not seem to gain carbon or energy from this reaction, it would be considered an anaerobic cometabolic process. Most importantly, however, this work suggests that biotransformation may play a role in PFAS fate and treatment in the future.

Other molecular traits that may decrease a chemical's biodegradability include high molecular weight, low water solubility, and extensive branching. As molecular weight increases to more than approximately 500–600 g per mole (g mol^{-1}), chemical biodegradability tends to decrease markedly. This trend reflects, in part, the inability of large molecules to enter the microbial cell. In some instances, extracellular enzymes produced by bacteria or fungi can initiate an attack on a large molecule, breaking it into smaller products that can then be metabolized further. For example, it is large size that prevents the biodegradation of many organic polymers that constitute plastics, such as polyethylene and polystyrene. If reduced to a molecular weight of less than 500 g mol^{-1} from their typical molecular weights of a few thousand to more than $100,000 \text{ g mol}^{-1}$, many of these polymer structures are biodegradable. Molecular branching also tends to reduce chemical biodegradability because molecular branches tend to sterically interfere with the common degradative enzymes used by microorganisms. For example, many alkanes are transformed by bacteria through the sequential oxidation and cleavage of two carbon molecules at a time, in a process known as "beta-oxidation". During this process, the alkane is sequentially oxidized (usually at the terminal carbon) to an alcohol, an aldehyde, and then an aliphatic acid. The acid is then cleaved to form acetyl-CoA, which the cell can utilize for energy. This beta-oxidation process continues until the alkane is completely degraded to acetyl-CoA. Branching of the alkane, particularly branching with one or more methyl groups, can block the two-carbon cleavage of beta-oxidation, causing an otherwise biodegradable molecule to become recalcitrant. For this reason, branched alkanes, such as pristane and phytane, tend to be among the slowest molecules to biodegrade during a crude oil spill. These molecules are frequently employed as internal standards to assess the biodegradation of other, more labile, components of crude oil after an environmental release.

Environmental factors affecting biodegradation

A compound that is readily metabolized in a laboratory may escape breakdown and persist unexpectedly in the field, even if an organism capable of causing its degradation is present. Unless pollutants are accessible to microorganisms and environmental conditions are conducive to microbial growth, contaminants will not undergo biotransformation and may remain in soil for extended periods. Thus, the extent of chemical biodegradation will depend in large part upon the physical, chemical, and biological properties of a contaminated site. A number of important factors influencing the growth of microorganisms and therefore biodegradation are described below.

Bioavailability

Contaminants released into soil will not be biodegraded if they are biologically unavailable. Even the most labile compound may persist if it does not come into contact with microorganisms. Bioavailability of a compound can be reduced if the compound is sorbed to soil particles, entrapped within the soil matrix, or dissolved in a nonaqueous solvent (Fig. 5).

Fig. 5 Representation of different potential states of an organic pollutant (cyclohexane) in a soil environment. (Not drawn to scale.) NAPL, nonaqueous-phase liquid.

Sorption

Chemical compounds can bind to solid surfaces through the actions of several attractive forces (Schwarzenbach et al., 2016). In some instances, a compound will adhere to the outer surfaces of soil particles in a process known as “adsorption.” “Absorption” refers to retention within the interior matrix of a solid particle. In either case, a compound partitions from a liquid phase (usually from water) onto or into a solid phase. Typically, the nonspecific term “sorption” is used to describe this phenomenon. Since compounds must generally be in an aqueous phase and enter the microbial cell to be subject to biodegradation, sorption often increases the resistance of a contaminant to biological attack. After a given period in a soil, a pollutant establishes an equilibrium between the sorbed and the aqueous phase. The extent of sorption at equilibrium, as quantified by the pollutant’s sorption coefficient (K_d), reflects the characteristics of both the pollutant and the soil matrix. When comparing pollutants of a single structural class (e.g., polycyclic aromatic hydrocarbons, PAHs), those molecules with higher K_d values, which tend to be primarily present in soils in the sorbed phase, generally biodegrade more slowly than those with lower K_d values. To enhance contaminant desorption, some bacteria and fungi have been observed to produce extracellular biosurfactants. The release of these surfactant molecules can increase the rate and extent of pollutant desorption and, subsequently, accelerate contaminant biodegradation.

Clay minerals and soil organic matter contain the principal sites to which contaminants can sorb. Charged compounds such as cationic pesticides (e.g., diquat) are often retained by clay minerals. Nonpolar organic molecules, on the other hand, tend to associate with soil organic matter through both adsorption and absorption. For example, PAHs such as phenanthrene, anthracene, and pyrene are subject to sorption and diminished availability due to their interactions with humic materials. In some instances, strong adsorbents such as biochars, activated carbon compounds, and clays are specifically added to soils and other media to enhance the sorption and subsequently reduce the bioavailability of difficult-to-biodegrade organic compounds, such as PFAS.

Entrapment within the soil matrix

Extended residence time in soil, or aging, can cause pollutants to undergo a time-dependent decline in bioavailability as they slowly move from positions within the soil that are accessible to organisms into positions that are inaccessible (Ren et al., 2018). Nonpolar organic pollutants, for example, can diffuse deeply into hydrophobic regions of soil organic matter and, as a result, evade microbial cells that might otherwise degrade them. Other compounds may diffuse into soil nanopores, thus becoming physically protected from metabolism by microorganisms. Although the details of the mechanisms involved vary, a compound that has moved into remote sites is said to be “sequestered” in soil.

The degree to which sequestration occurs depends upon a number of variables, including the properties of the soil and the contaminant involved. Studies continue to define the soil properties most responsible for the entrapment of contaminants; however, soil organic matter content appears to be positively correlated with the extent of chemical sequestration. Likely, soil structure also plays a key role in the sequestration of some contaminants. Contaminants may be more protected from biodegradation in soils possessing highly developed aggregates than in less structured soils. The chemistry of a contaminant is clearly critical as well. Analyses suggest an inverse relationship between a compound’s water solubility and its potential for sequestration, but the relative importance of this and other properties remains largely unknown. Pollutants for which sequestration has been observed include the PAHs phenanthrene and anthracene, and various pesticides, such as 1,2-dibromoethane (EDB), DDT, and chlordane, among others.

Nonaqueous-phase liquids

Many relevant environmental contaminants are present in soils dissolved in non-aqueous solvents. For example, crude oil is a nonaqueous-phase liquid (NAPL) composed of multiple compounds, most of which have very low water solubility. Since microorganisms are typically active in the aqueous phase only, pollutants in NAPLs can escape biodegradation. The extent to which an individual compound dissolved in a NAPL will be degraded depends upon numerous factors, including the rate of partitioning between the nonaqueous and aqueous phases, the equilibrium concentration of the pollutants in the aqueous phase, the nature of the interface between the two phases, and the toxicity of the NAPL to the microorganisms responsible for degradation. Although individual compounds within a NAPL tend to be degraded at different rates, in general, pollutants in a nonaqueous phase can be extremely persistent.

Nutrient availability

Heterotrophic microorganisms in soil require a number of macro- and micronutrients, an energy source, and an electron acceptor to grow (Madigan et al., 2018). Often, a contaminant provides a carbon or energy source, but all other requirements must be fulfilled if biodegradation is to occur. A biodegradable compound released into a nutrient-poor soil (e.g., little available nitrogen or phosphorus) can persist unexpectedly, because microorganisms that possess the capacity to metabolize the contaminant cannot grow to sufficient cell numbers. In some instances, as during the biodegradation of the explosives 2,4,6-trinitrotoluene (TNT) and RDX under nitrogen-limiting conditions, specific organisms can degrade an organic compound to obtain a scarce noncarbon nutrient (in this case, nitrogen). Some organic phosphorus-containing compounds, such as triethylphosphate (TEP), can also be utilized by microorganisms to obtain phosphorus under conditions in which the compound is unavailable for microbial growth.

During bioremediation of soil contaminants, the addition of nitrogen, phosphorus, or other limiting nutrients is often conducted to stimulate the growth of indigenous or added microorganisms.

pH

Some bacteria, fungi, and particularly archaea can survive and grow under very acidic or alkaline conditions, but the optimum pH for most soil microorganisms is near neutrality. Unless organisms have evolved to live under extreme pH conditions (e.g., thermophilic or acidophilic bacteria or archaea), both high and low pH can lead to the denaturing of microbial enzymes and the hydrolysis of other crucial cell components. It is therefore not surprising that biodegradation tends to be fastest near pH 7 and slows considerably as the pH becomes appreciably more alkaline or acidic. In addition to its direct effect on cells, pH will also influence the chemistry of ionizable contaminants in soil. The sorption and subsequent bioavailability of cationic pesticides (e.g., paraquat, diquat), basic pesticides (e.g., atrazine), and acidic pesticides (e.g., 2,4-D, dicamba) will depend in part on the pH of the soil solution in which they are present. To enhance microbial growth and biodegradation, bioremediation protocols sometimes include chemical treatment of the contaminated soil (e.g., by lime addition) to adjust pH to the optimum for the biodegradative organisms.

Temperature

The growth of microorganisms is highly dependent on temperature, and the prevailing temperature in soil is an important factor controlling the rate and extent to which a contaminant is biodegraded. Most microorganisms in soil are mesophilic, with temperature optima ranging from approximately 25 °C to 35 °C, and growth possible from 15 °C to 45 °C. Therefore, optimal temperatures for biodegradation in soils tend to be within the best growth range for these organisms, with rates increasing as temperatures increase within this range. However, it should not be implied that biodegradation processes cease below 15 °C or above 45 °C. There are many bacteria and archaea that are psychrophilic, with growth optima less than 15 °C, and those that are thermophilic, with growth optima exceeding 40 °C and sometimes with extremes as high as 65 °C. These organisms can be responsible for contaminant biodegradation in extreme environments such as in polar climates (for psychrophiles) or in compost (for thermophiles). In fact, thermophiles have been applied in numerous *ex situ* bioremediation applications due to their ability to rapidly degrade some contaminants. Please see later section entitled *Climate Change and Biodegradation* for additional details.

Water content

The moisture content of soil influences the growth and metabolism of microorganisms. As with the other abiotic factors discussed above, tolerance to desiccation varies among organisms. Environments characterized by low water content tend to support only limited microbial activity. The optimal activity of most microorganisms occurs at soil moistures ranging from 60% to 80% of the soil water-holding capacity (WHC). Biodegradation can be very limited in dry soils, and pollutants may persist in arid or drought-affected regions longer than in wet areas. Conversely, excessive moisture can limit oxygen diffusion in soil and cause a shift from aerobic to anaerobic conditions. As previously noted, the absence of available oxygen can severely inhibit the disappearance of some pollutants and pesticides, although such conditions may be necessary to promote the degradation of other compounds (e.g., by reductive dechlorination).

Presence of appropriate microorganisms

Microorganisms capable of performing a given biodegradation reaction are frequently indigenous in soil. For example, bacteria that aerobically degrade the common gasoline components benzene, toluene, ethylbenzene, and xylenes (BTEX) are ubiquitous in most surface soils. If these contaminants persist for long times in a soil, it is likely that environmental factors such as nutrient availability, oxygen levels, contaminant availability, or the presence of toxic co-contaminants are impeding the biodegradation process. For some contaminants, however, biodegradative populations are less universally distributed or are present only at very low densities. For example, the gasoline oxygenate methyl *tert*-butyl ether (MTBE) has been observed to biodegrade readily in some aerobic soils and aquifers but to be highly persistent in others. In environments where the contaminant persists, the absence of a biodegrading population has been cited as a key factor limiting its destruction. Bioaugmentation has been used at some sites to promote MTBE biodegradation. Similarly, the absence of a specific dehalorespiring microorganism (*Dehalococcoides mccartyi*) has been cited as the key factor determining the extent of biodegradation of PCE and TCE in some anaerobic environments (see Fig. 3). If this organism is absent, dechlorination of PCE (or TCE) appears to stall at *cis*-DCE or VC, rather than progressing all the way to ethylene. Bioaugmentation has now been used to add this organism to thousands of sites to enhance chlorinated solvent biodegradation.

Predation

Bacteria are subject to predation by protozoa. Such grazing can influence the biodegradation of soil contaminants, with both inhibition and stimulation possible. Predation by soil protozoa can reduce the number of cells metabolizing a contaminant and cause a decline in the rate at which the compound disappears. Alternatively, due to the positive effect predation has on nutrient availability, grazing may stimulate the growth of microorganisms. Through their metabolism of microbial cells, protozoa release available nitrogen, phosphorus, and other nutrients back into soil and, consequently, stimulate the surviving microbial cells to grow

faster. The dynamics of predator-prey relationships in soil are complicated and are not completely understood. Whether predation decreases or increases biodegradation rates depends upon a number of factors, including the starting density of the bacterial prey and predator organisms, the size of the cells, and the properties of the soil in which the organisms live.

Presence of other compounds

Microorganisms metabolizing a pollutant can be affected by the presence of other soil contaminants. In particular, it is not uncommon for a co-contaminant (such as a heavy metal or low molecular weight hydrocarbon) to be present in toxic concentrations in a heavily polluted soil, thereby inhibiting the biodegradation of a target compound by killing the biodegradative population. An organism may also preferentially use a compound other than the contaminant as a carbon or energy source and, as a result, biodegradation of the selected contaminant can be slowed. Alternatively, the presence of a second compound can stimulate microbial activity and accelerate biodegradation. For example, bioremediation of a compound that is cometabolized can be enhanced by the addition of a substrate on which the cometabolizing microorganism can grow. The addition of biphenyl to soils has been observed to enhance the rate of degradation of some of the less-chlorinated PCBs. In some instances, however, the growth substrate will actually inhibit degradation of the cometabolized compound owing to competitive enzyme inhibition. The presence of toluene above a given concentration, for instance, can reduce the rates of TCE cometabolism by specific toluene-oxidizing strains. For bioremediation applications, intermittent addition of the growth substrate may be necessary to promote degradation of a cometabolized pollutant.

Plants

Plants play a critical role in the biodegradation of organic contaminants (Azaizeh et al., 2011). Growing plants cause many changes to soil structure, chemistry, and microbiology. Plants with extensive root networks disrupt soil aggregates, creating networks for penetration of oxygen and water, as well as new surfaces for microbial growth. Perhaps most importantly for biodegradation and bioremediation, plant roots excrete a wide variety of compounds that include enzymes, surfactants, growth factors, amino acids, carbohydrates, and carboxylic acids, among others, which are known collectively as “root exudates”. The plant root environment or “rhizosphere” typically harbors a larger and much different microbial community than the surrounding soil matrix, and one which can have very different capabilities in terms of contaminant biodegradation. A wide variety of contaminants including chlorinated solvents, chlorinated phenols, herbicides, petroleum hydrocarbons, polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and explosives have all shown enhanced rates of biodegradation in rhizosphere compared to non-rhizosphere soils. These effects may be related to one or more factors including higher oxygen, carbon and inorganic nutrient levels, presence of primary organic substrates for cometabolism, greater density or diversity of degrading organisms, enhanced solubilization and bioavailability of the contaminant (e.g., due to surfactant effects), and changes in pH or soil water content. The observation of enhanced biodegradation in the rhizosphere combined with plant uptake of various contaminants (with or without enhanced degradation by plant enzymes) has led to the development of phytoremediation as a soil and water remediation technology over the past few decades. This has progressed to the development of transgenic plants that express microbial enzymes capable of biotransforming contaminants upon plant uptake.

Potential impacts of climate change on biodegradation

Decades of research have linked anthropogenic releases of greenhouse gases to several phenomena, notably, a steady increase in Earth’s average temperature since the late 19th Century, shifting climates, rising sea levels, and decreasing ocean pH. Some of the likely consequences of these changes for both natural and anthropogenic systems, including accelerated extinctions, redistribution of precipitation, and loss in soil fertility and food production, have been studied extensively; on the other hand, potential effects on biodegradation and bioremediation are not as well understood.

It is probable that global warming will influence rates and extents of contaminant biodegradation as well as bioremediation success at contaminated sites. Simply put, if the bacteria, archaea or fungi, possessing the ability to metabolize synthetic pollutants, grow successfully at a particular location, then biodegradation will proceed, perhaps even at accelerated rates; if the relevant microorganisms are inhibited by environmental changes, those contaminants will persist. The integration of natural systems presents challenges when predicting whether clean-up will be enhanced or impeded by altered conditions. However, many of the factors influencing biodegradation processes discussed in the previous section (e.g., temperature, pH, water content) may be influenced by climate change, and thus, may impact biodegradation and bioremediation in the future. Here we briefly summarize some important considerations.

Changes in pH

As noted above, soil microorganisms are most effective at their optimum pH. Higher levels of atmospheric carbon dioxide drive diffusion of this greenhouse gas into all of Earth’s water, including that in soil, and lowers its pH. In addition to the possible changes to microbial community structure that would follow, recalcitrant pollutants such as TCE could become even more persistent because of the inverse relationship between acidity and the rate of biological dichlorination reactions of such compounds.

Changes in Earth's temperature

Many models predict that the average temperature on Earth will increase by 1–2 °C before the year 2100, and in some areas, an increase in 1.5 °C has already occurred compared to pre-industrial times (Buis, 2019). The global climate system is quite complicated, however, so changes are not expected to be uniform. Indeed, although nearly all areas will experience appreciably warmer conditions, a few could become cooler. Our focus will be on the effects of higher temperature.

- *Increased reaction rates.* Like all chemical reactions, microbial transformations are positively correlated with temperature. If it did not interact with any other environmental variables, modest warming would, in principle, speed up the clean-up of contaminated sites (although it is unclear if a rise of 1–2 °C will have a substantive impact—those areas affected by more dramatic warming could see appreciable increases). Since temperature changes clearly do *not* occur in isolation, predictions of biodegradation rates must account for mutual influences among multiple variables (some of the most critical are described below).
- *Oxygen availability.* As described earlier, the biodegradation of many important soil pollutants depends on the actions of aerobic organisms, thus reduced O₂ concentration is of great concern. Elevated temperatures may diminish the amount of oxygen present in some systems for several reasons. First, because dissolved oxygen (DO) is inversely proportional to water temperature, soil water could become more hostile to oxygen-using bacteria and fungi. Second, warming will drive the melting of high-latitude permafrost and the release of sequestered soil organic matter (SOM); demand for oxygen will rise as more and more SOM is accessible for decomposition, potentially slowing degradation of synthetic pollutants that undergo aerobic biodegradation while accelerating rates for those that are subject to anaerobic degradation processes. Third, over time, aerobic microorganisms that both dominate their soil ecosystems and possess the capacity to metabolize pollutants could be replaced by species adapted to low-oxygen conditions, again shifting the balance of degradative processes from aerobic to anaerobic. We will return to this and other ecological-based considerations shortly.
- *Water availability.* Increased average temperatures have led to more net precipitation over terrestrial areas, although there is a great deal of variability with location. Some, like southern California (United States) have seen declining precipitation since 1901, whereas portions of upper mid-western and northeastern US states have received more rainfall during the same period (USEPA, 2016). Much evidence suggests that plant and microbial production would increase with modestly higher water availability; the problem is complex, because higher rates of evaporative losses with warming could effectively drive out any extra soil water. If water availability in soil decreases, desiccation-resistant organisms without the ability to metabolize pollutants could begin to dominate ecosystems. Alternatively, as described above, saturated soils that become anoxic will not support aerobic metabolism and very likely will slow the rate of aerobic degradation of pollutants, while potentially accelerating rates for those that undergo anaerobic biodegradation. Whether alterations in soil moisture content will be large enough to initiate relevant changes remains an open question.
- *Sea level rise.* Due to thermal expansion of sea water and melting of land-based glaciers, sea levels are expected to rise by between 0.5 and 0.8 m in the next 80 years (Oppenheimer et al., 2019). Clearly, high-elevation terrestrial areas will not be directly impacted by these changes. However, since human populations are disproportionately concentrated in coastal areas, the inundation of soil in low-lying areas with sea water could lead to profound environmental effects and disruption of biodegradation processes.
- *Changes to community structure.* Organisms dominating a soil ecosystem may lose their advantages as environmental conditions change. The problem is a nuanced one, though, because not all species are equally resilient. The effects of the resultant changes on microbial interactions (e.g., predation and competition) on biodegradation clearly will vary, and, like the concerns described above, are difficult to predict. Even without a change in the identity of species in a community, the activities of existing organisms will surely be affected.
- *Disruption of nutrient cycling.* Microbial activity is critical to the maintenance of soil ecosystems. For example, fixation, predation, and decomposition increase the biological availability of vital nutrients such as carbon and nitrogen. Changes in environmental conditions could put stress on the communities responsible for these processes and limit the growth of organisms carrying out biodegradation.
- *Changes in plant-microbe interactions.* The relationships between plants and microorganisms dictate success or failure of the participating organisms, affect soil fertility, and, as noted above, influence pollutant fate. A complex matrix of interacting variables limits our ability to generalize likely outcomes, but it is reasonable to expect that disruptions in mutualism, commensalism, competition, amensalism, parasitism, and predation could have appreciable effects on both microbial- and phytoremediation.

Summary

Biodegradation is an important process by which chemical contaminants may be removed from soil. Microorganisms have a remarkable ability to metabolize an extremely diverse range of synthetic compounds and can be invaluable in the remediation of contaminated environments. The rate and extent of biodegradation of a given contaminant in soil depends on a number of variables, including chemical structure, contaminant bioavailability, and an array of environmental factors, such as nutrient availability, pH, temperature, soil moisture, presence or absence of plants, predation, and the types and concentrations of

co-contaminants. Impacts of climate change on biodegradation processes are hard to predict, but increasing temperatures are likely to impact many different variables, including water, nutrient, and oxygen availability, which can subsequently influence rates, extents, and routes of pollutant biodegradation.

Abstract

Manure is associated with many benefits including increased soil microbial diversity and biomass - important indicators of soil conditions. Management of manure has, however, been associated with issues of air and water quality as well as threats to plant, animal, and human health. To mitigate some of these environmental concerns, various treatment strategies involving microorganisms have been developed. Microorganisms and various invertebrates break down organic compounds in manure, transforming them into energy and plant available nutrients. This chapter explores the biology associated with manure management, including its storage, composting and treatment, and emphasizes effect on certain species of soil organisms.

Glossary

Acetogenesis A stage in anaerobic digestion in which acetate is produced through the reduction of CO₂ or organic acids.

Acidogenesis A chemical process and stage in anaerobic digestion where sugars and amino acids are degraded to products such as alcohols, fatty acids, and volatile fatty acids.

Denitrification The process through which nitrate is reduced to gaseous forms of nitrogen under anaerobic conditions.

Methanogenesis A process that involves the reduction of carbon compounds under and is facilitated by archaea under anaerobic conditions.

Nitrification The sequential oxidation of ammonia to nitrite and of nitrite to nitrate.

Prion An abnormally folded protein that can transmit its abnormal folding pattern to normal proteins of the same kind.

Virulence The degree of harm a pathogen may cause to a host.

Key points

- Livestock manure when added to soil can increase microbial species richness and diversity
- Treatment and storage of manure affect the chemical and biological composition of manure
- Manure application may affect soil fauna positively or negatively depending on its effect on carbon, ammonia concentration, metal content, and salinity
- Manure can suppress disease causing pathogens in soil by enhancing pathogen antagonistic microorganisms

Introduction

Since early human civilization, animal manure has been used as a soil amendment. There is evidence of its use for growing crops as far back as 6000 BCE (Bogaard et al., 2013). Manure offers many physical, chemical, and biological benefits to soil and therefore to crop production. The application of manure to soil has been associated with improved hydrological characteristics, improved soil structure, increased organic matter, improved soil fertility, and increased microbial activity. Soil microbial activity and thus microbial processes in the soil have been identified as important indicators of soil condition. A healthy soil is the foundation of agriculture and the need for productive soils will only increase as the demand for food increases. However, intensification and expansion of agriculture around the world has led to the degradation of soils. Soil microbes govern nutrient cycling, break down pollutants, improve soil structure, and mediate organic matter decomposition. Livestock manure, when added to soil, can increase microbial species richness and diversity. These microbial species may play key roles in organic matter decomposition and plant growth promotion. However, there is increasing concern that manure could be a source of antibiotic resistance, which threatens human and animal health. When antibiotics are administered excessively to animals through feed or other means, antimicrobial resistant bacteria and genes can end up in the soil with animal feces. In addition, handling and application of manure has been associated with water and air quality issues. Thus, although manure provides many benefits to the soil, caution must be taken in handling, storage, and land application. Using manure to benefit the soil inevitably requires consideration of ways to mitigate any threats against soil and water quality. This chapter explores the biology associated with various steps in manure handling and treatment including storage, composting, and anaerobic digestion. This chapter also reviews the biological benefits, following manure application to soil, including organic matter, carbon content, and the dynamics of macro- and microorganisms already present in the soil.

Trends in manure production and application

Animal manure has long been used as a nutrient rich soil amendment. The discovery of manure as a nutrient source was likely more by happenstance with early farmers noticing enhanced crop growth in areas where dung had accumulated during the raising of animals. On a global scale, livestock production has increased greatly since the 1960s. In various developed countries, the average livestock density, expressed in the number of animals ha^{-1} has been steadily increasing, a development that has led to surplus plant nutrients on farms. In developing countries animal production is generally not as intensive but, as these countries develop, their production systems will likely become more intensive. The nature of the animal production system directly affects the amount of manure available for use as a soil amendment. The increase and concentrated geographical distribution of concentrated animal feeding operations (CAFOs) has resulted in excess manure nutrients and raised concerns about point and nonpoint source pollution of air, soil, and water. These concerns have increasingly brought manure handling practices to the attention of regulators and advisors. Globally, there has been a decline and stabilization of land applied manure N from dairy and non-dairy cattle since the early 2000s (Fig. 1). This trend is likely a function of the more concentrated production of manure in certain hot spots, with a decline in manure production being experienced in other regions. The type of animal manure applied to land depends on the manure most available in an area. It is a fact that animal production by species differs between regions; for example, sheep and goats are very common in Asia and Africa, whereas chickens are more prevalent in Asia and North America (Table 1).

Manure composition as affected by storage and treatment

The collection, storage, treatment, and land application of manure involves many biological processes, their by-products, and a diverse array of microbial species. Manure is commonly composed of urine, fecal matter and bedding materials thus containing proteins, fats, and carbohydrates. The biochemical composition of manure depends on animal species, animal feeding practices, the housing system, and the manure collection system (Table 2). It is well documented that, during handling, storage, and land application of manure, volatile organic compounds (VOC's), methane (CH_4), ammonia (NH_3), hydrogen sulfide (H_2S), and nitrous oxide (N_2O) are emitted into the atmosphere. The volatilization of ammonia and nitrous oxide emission result in a net loss of nitrogen (N), a nutrient needed in large amounts by crops. Ways to reduce or mitigate some of the threats associated with manure handling are to minimize uncontrolled losses of manure by building proper manure storage structures, treating manure through composting or anaerobic digestion (AD), controlling the timing, amount, method, and placement of manure when applied to land.

Storage

The purpose of manure storage is to contain the manure, process wastewater, and prevent contaminated runoff until it can be safely applied to land. There are various manure storage systems such as stockpiling of solid manure, tank or lagoon storage of liquid manure. Stockpiling is the practice of piling solid manure either inside in a stacking shed or outside, where it ages until it is land applied. Unlike composting, this system of storage is passive and anaerobic. Many of the characteristics associated with raw manure like nutrient concentrations and proportions, odor, and the presence of weed seeds and pathogens remain in stockpiled manure. Nevertheless, anaerobic biological processes can lead to the production of organic acids, acetic acid, methane, and carbon dioxide (CO_2). There are many types of tanks to store manure in liquid form including under-floor pits, fabricated steel or concrete storage

tanks, ponds, and lagoons. Lagoons are earthen structures that differ from storage tanks or ponds in that they provide treatment in addition to storage. The type of biological processes that occur in the lagoon depend on variations in light, temperature, access to oxygen, and the presence and type of organic matter. As a function of the presence or absence of oxygen, lagoons may contain aerobic, anaerobic, or facultative organisms (Pfoest et al., 2000). Both lagoons and stockpiles for manure storage and processing harbor facultative microbes in that both aerobic and anaerobic conditions exist.

Manure treatment

Treatment of manure involves a deliberate attempt to reduce the mass of the manure, control pathogens, concentrate or reduce nutrients, or produce by-products, such as compost or energy. Treatment of manure thus affects the chemical and biological composition of the manure and consequently how manure or its by-products will affect the soil to which it is applied.

Anaerobic digestion

Anaerobic digestion (AD) is a process through which organic feedstocks, including food wastes, biosolids or sewage sludge, and livestock manure are broken down in the absence of oxygen. The purpose of AD is two-fold; firstly, to produce renewable energy, biogas, thereby reducing the use of fossil fuels and secondly, to decontaminate biodegradable wastes allowing them to be safely used as a soil amendment. Biogas consists primarily of methane and carbon dioxide, but may also contain sulfur compounds, ammonia, volatile organic compounds (VOCs), and particulate matter. Microbial activity in AD systems is influenced by the composition of feedstock and operation conditions such as temperature, pH, and retention time. The efficiency of organic matter conversion to methane decreases with increasing total solids, while initial large concentrations of ammonium might inhibit methane production. Anaerobic digestion consists of hydrolysis, acidogenesis, acetogenesis, and methanogenesis and each one of these phases is carried out by a different group of microbes (Meegoda et al., 2018). Hydrolysis involves extracellular enzymes from hydrolytic bacteria degrading organic material into smaller, more soluble compounds such as lipids, proteins, and soluble carbohydrates. Unlike methanogenic species, which thrive at neutral pH, hydrolytic and acidogenic microorganisms are favored by a more acidic environment. During acidogenesis, products from the hydrolytic processes are fermented to short chain volatile fatty acids (VFAs), such as acetate and propionate in addition to gaseous products, such as, carbon dioxide, hydrogen, and ammonia. In acetogenesis, bacteria known as acid formers, convert products from the hydrolytic process into organic acids, such as acetic acid, butyric acid, propionic acid, ethanol and carbon dioxide and hydrogen. During the next step in the process, methanogenesis, is conducted by a group of archaea called methanogens. The production of methane in AD is thus a complex process driven by various microorganism and impacted by variables that when not adequately controlled can inhibit microbial activity. In agricultural production, anaerobic digestate can be used as soil amendment, fertilizer, and bedding for livestock.

Composting

Composting is different from stockpiling in that it is an actively managed process. Composting is an aerobic microbial process in which organic matter is transformed into a nutrient rich and stable product that can be applied to soil as a fertilizer and soil conditioner. During this process bacteria and fungi break down the organic matter and produce carbon dioxide, water, heat and stabilized organic matter. If composting is done correctly, the final product, compost, should be free of pathogens and viable seeds. Composting is not a continuous homogenous process but is rather variable with changing temperature, pH, oxygen flow, and moisture. Variable growth conditions favor different organisms growing and thriving at the various stages as organic matter breaks down. There are several types of composting, e.g., onsite composting, vermicomposting, aerated windrow composting, aerated static pile composting, and in-vessel composting. Different groups of organisms are involved in composting including macro- and mesofauna and microorganisms. The activity and abundance of microbes in compost is heavily impacted by various physicochemical properties of compost including the manure or bedding material used, water soluble organic carbon, temperature, and moisture. Manure type has been shown to significantly impact the diversity of microbial communities at different stages during composting. When it comes to manure type for example, Wan et al. (2021) found that sheep and cattle manure composts harbor more diverse microbial communities than pig and chicken manure composts, at both the beginning and the end of the composting process. Temperature is arguably the most important physicochemical variable in the composting process. Composting is categorized into three different stages as a function of the changing temperatures. The different phases, in chronological order, are the mesophilic phase, thermophilic phase, and the maturation phase. Various groups of microbes dominate at these different temperature regimes. The mesophilic phase is characterized by rapid growth of microorganisms facilitated by favorable conditions, with temperatures ranging between 25 and 40 °C. The thermophilic phase, with temperatures >40 °C, favors a high rate of decomposition with a rapid growth of thermophilic microorganisms, while the maturation phase includes cooling and stabilization of the process. Although both fungi and bacteria are involved in the decomposition and transformation of compost, bacteria dominate as they have higher thermal tolerance than fungi (Biyada et al., 2021). Both microbial biomass and basal respiration, a parameter for decomposition, decline with compost age. The relative abundance and diversity of bacteria and fungi has been shown to change during composting, with a decline in bacteria from the thermophilic to the maturation phase likely linked to a decline in available nutrients.

Effect of manure on soil conditions and biodiversity

That many soils around the world are degraded is common knowledge. Soil is considered to degrade when its physical, chemical, and biological characteristics deteriorate due to natural or human influences, leading to loss of important soil ecosystem functions. Various practices can be used to mitigate or reverse some impacts related to soil degradation some of which are reduced tillage, retention of crop residue, and the addition of organic soil amendments such as manure. Land application to meet crop nutrient requirements is by far the most widespread and longstanding use of animal manures. In addition to its impact on soil fertility and soil physical characteristics, manure also has a significant impact on biological properties including organic matter and carbon (C) content, and the abundance, diversity of organisms.

Soil organic matter and soil organic carbon

Soil organic matter (SOM) plays an important role in maintaining the ability of soil to provide a host of ecosystem services, including sustainable productivity. Soil organic matter has been associated with different benefits including a decrease in erosion and runoff, improved soil structure, and improved water infiltration. Moreover, there is an intimate relationship between organic matter and soil organisms, as they are the living component of SOM. Increasing SOM or SOC through manure application is a function of different factors such as the source, the percent solids, and bedding material used. Bedding materials in animal production facilities might include sand, sawdust, wood shavings, straw, or compost. Producers select bedding material for their stalls based on comfort and health of the animals, cost, availability, and labor efficiency. Bedding will ultimately affect the composition of the manure, its carbon to nitrogen ratio, its mineralization, and its effect on soil. Manure containing bedding material that has a large organic carbon content may result in a more significant increase in SOM and carbon (C). Additional factors, which will affect the degree of C increase, are weather related and include soil moisture and temperature, but the rate, frequency, and method of application also play a role. High rates of manure applied over several years will result in a greater increase in SOM compared to short term manure application. The carbon contained within SOM is receiving increased attention due to its role in mitigating the effects of climate change. It has been reported that the application of animal manure can potentially increase SOC stock by 32–50% (Gross and Glaser, 2021). However, given the many factors that this depends on it is reasonable to use caution in making estimations about the degree to which manure will increase C levels in soil. Soil organic carbon (SOC) is an important indicator of soil condition as it is also associated with microbial biomass. Soil respiration is an essential part of the carbon cycle and an important indicator of microbial activity in soil, although other processes such as root respiration are also involved in the production of CO₂ in soil. A high C: N ratio in manure and the slow release of nutrients from manure may cause a decrease in CO₂ flux when first applied. However, over time as microbes continue to decompose the manure, increased CO₂ flux might be detected. Although indicative of biological activity, soil is believed to be one of the most species rich habitats among terrestrial ecosystems harboring millions of species of organisms. Species may include archaea, algae, bacteria, fungi, nematodes, and a wide array of fauna.

Macro- and mesofauna

According to estimations, soil animals may represent roughly 23% of the total diversity of living organisms (Decaëns et al., 2006). There is generally a positive relationship between land applied manure and the abundance and diversity of fauna in soil as manure functions as a food and nutrient source for these organisms. However, manure may also have an adverse effect on the abundance and diversity of soil organisms depending on its biochemical composition. Macrofauna, the largest size class of invertebrates with body widths greater than 2 mm, are often thought of as the most familiar group of fauna as they can be seen with the naked eye. This group of fauna includes orders such as isopods, centipedes, millipedes, spiders, beetles, termites, ants, and earthworms with each playing a unique role in organic matter breakdown and nutrient cycling. Earthworms play a role in incorporation of organic material in soil, the formation of soil pores and stable macroaggregates, and greater nutrient availability. An increase of earthworms due to manure application is mainly attributed to the carbon in manure which functions as a food source for the earthworms. However, ammonia concentration, metal content, and salinity are among factors that may affect earthworms negatively. High levels of ammonia in manure are toxic to earthworms and may reduce their population size until conditions become more favorable (Edwards and Bohlen, 1996). However, the ammonia content of manure depends on different factors including, animal type, feed, manure storage and management, and whether the manure is liquid or solid. Poultry manure, for example, contains significantly more ammonia in comparison to beef or dairy manure and therefore would present a greater risk to soil fauna if not managed properly. In addition, long-term application of manure at high rates presents a salinization risk, a condition that generally affects soil fauna adversely. Electrical conductivity is a measure of the ability of soil to transmit an electrical current. Although primarily linked to potassium ions, this variable is used to estimate dissolved salts in soil. An increasing EC with the application of increasing rates of manure is not uncommon. An EC above $>4 \text{ mmho cm}^{-1}$ has been shown to inhibit the growth of most plants and affect many other soil biological factors. Mineral salts are an important component of livestock nutrition. In fact, several health issues including reduced productivity and a reduced appetite are associated with a lack of salt in the animal diet. Feeding large amounts of salt to livestock ultimately results in high amounts of salt in the animal excrements which can buildup in the soil. Similarly, when animal feed contains trace minerals such as cobalt (Co), copper (Cu), iron (Fe), and zinc (Zn) above dietary needs, the potential for heavy metal contamination of soil and water increases. These trace minerals are added as a supplement to animal feed to support proper growth and development of the animals. Heavy metal contamination and high salt concentrations have an inhibitory effect on the growth and abundance of certain species of earthworms and other fauna in soil. Mesofauna, of which acari (mites) and collembolans (springtails) are the predominant organisms, have also been found to be affected significantly by metal concentrations and other soil environmental factors. However, manure can affect variables of the soil environment differently and therefore may have different concurrent effects on organisms. For example, certain species of mites have been shown to be affected by metal pollution although not necessarily negatively when soil humidity and acidity are favorable (Manu et al., 2019).

Manure plays a role in various soil physical characteristics such as soil moisture, temperature, soil structure. These characteristics in turn may affect species richness and diversity of soil organisms. Although conclusions vary, manure application has been generally associated with greater soil water retention although this depends on the manure type and the bedding used. Decreasing soil moisture and droughty conditions have a negative effect on the population composition and numerical abundance of soil

fauna in which survival of the fittest becomes apparent. In general, it is highly likely that under drought conditions, the population of various species will show an abundance of drought resistance species and a reduction in the number of drought sensitive species. The maintenance or increase of soil moisture with the application of manure may thus promote a more balanced population of fauna species as such conditions facilitate the growth of a wider variety of species. However, although there is general agreement that the application of manure no matter the animal type, or the form of the manure whether liquid or solid, increase the abundance and density of fauna, the diversity of manure and manure management might make the extent of the effect somewhat challenging to predict. Importantly, during the treatment of manure specifically during composting, fauna might make their home in the compost pile which upon application can be transferred to the soil. Common fauna present in compost are mites, ants, snails, beetles, and earthworms.

Microbes involved in nitrogen fixation, nitrification, and denitrification

Nitrogen is an essential element for plant growth and is limiting in most ecosystems, although abundantly present in the atmosphere mostly as N gas (N₂). Nitrogen is a component of various compounds in plants and other organisms some of which are chlorophyll, proteins, and amino acids. The N is thus crucial for the productivity and proper functioning of ecosystems. Hence, while manure affects many other microbes and microbial processes (Table 3), the focus in this section is primarily on microbes involved in processes concerned with N.

Specialized prokaryotes can fix atmospheric N and reduce it to ammonia using the enzyme nitrogenase. Biological N fixation contributes approximately 200 million tons of N to the earth's ecosystem annually (Shamseldin, 2022) and could thus represent significant N-fertilizer costs savings. Several prokaryotes involved in N₂-fixation include aquatic organisms such as cyanobacteria, symbiotic diazotrophs such as Rhizobium and free-living non-symbiotic diazotrophs, such as Azotobacter. Long-term application of manure can significantly increase the abundance of soil autotrophic azotobacters relative to untreated soil. Manure containing little C as a food source and N has been shown to support a smaller diversity of soil nitrogenase and N₂-fixing bacteria. Rhizobia form a symbiotic relationship with legumes which results in the formation of nodules on the roots. It is well known that large applications of available N, of which manure is an important source, inhibit biological N fixation. However, application of manure in addition to synthetic fertilizer has been shown to increase the number and dry weight of nodules in soybean (Nagwanshi et al., 2018). This is likely due to the slow release of available N from manure, its large organic C content, and the favorable conditions the manure creates for the rhizobia.

Table 3 Relative abundance of soil bacterial phyla with manure application.

Manure type	Relative abundance		Source
Swine slurry	Phylogenetic Group	%	Rieke et al. (2018)
	Acidobacteria	30–5 ^a	
	Actinobacteria	9–12	
	Bacteroidetes	2–17	
	Proteobacteria	12–39	
Composted manure	Verrucomicrobia	12–6	Peng et al. (2021)
	Acidobacteria	16.5–15.1 ^b	
	Actinobacteria	11.7–14.7	
	Bacteroidetes	8.4–7.8	
	Proteobacteria	26.7–29.6	
Poultry litter	Firmicutes	6.0–5.4	Jangid et al. (2008)
	Acidobacteria	17.7, 18, 19 ^c	
	Bacteroidetes	7.6, 5.8, 7.6	
	Proteobacteria	40.5, 41.9, 31.7	
	β-Proteobacteria	14.4, 16.5, 11.4	
Organic manure	γ-Proteobacteria	6.3, 4.3, 2.7	Tang et al. (2020)
	Acidobacteria	11–14 ^c	
	Actinobacteria	8–17	
	Proteobacteria	8–13	
	α-proteobacteria	8–11	
	Firmicutes	9–14	

^aNumber on left represents the abundance at application (day 0), number on right represents abundance at 108 days after application.

^bNumber on left is abundance at pre-season and number on right represents abundance after manure application. \$numbers represent three agricultural management systems, respectively conventional tilled cropland, hayed pasture, and grazed pasture with poultry manure applied.

^cReported as a range at different of manure relative to chemical fertilizer.

Agricultural soils have been claimed as one of the largest sources of anthropogenic nitrous oxide (N_2O) emission. The main pathway to produce nitrous oxide is through microbial nitrification and denitrification. Soil nitrification, the oxidation of ammonia to nitrate, is driven by ammonia oxidizing bacteria (AOB) and archaea (AOA) and plays an important role in the N cycle. Nitrification is commonly described as a two-step process consisting of the oxidation of ammonia to nitrite and the oxidation of nitrite to nitrate. Manured soils have been found to have significantly greater nitrification rates compared with soil to which no manure is applied. When compared with synthetic fertilizer treatments, manure treated soil may yield a greater abundance of AOA and AOB which can be attributed to the ammonium ions released from manure during decomposition and the favorable soil environment created when manure is applied. However, the sensitivity to NH_4^+ concentrations, can be variable among ammonia oxidizers and large concentrations may even inhibit ammonia oxidation and cause a shift in community composition (Princic et al., 1998). Denitrification is the sequential process where nitrate or nitrite are reduced toward N_2 by a number of groups of denitrifying archaea, bacteria and fungi producing nitric oxide (NO) and N_2O as intermediate products. The efficiency of denitrification is not 100% and it does not always end with the formation of dinitrogen. The reduction of N_2O to N_2 however, is considered a critical step in denitrification as the completion of this process reduces the potential for N_2O emission. Various bacterial species, such as *Pseudomonas* and *Bacillus* among others are involved in this sequential reduction of nitrate and nitrite. This process is encouraged with high nitrate concentrations, high C availability, and under anaerobic conditions. Specific fungal phyla that possess the ability to denitrify are Ascomycota and Basidiomycota. Manure and the application of other organic soil amendments has been associated with an increase in the abundance of nitrate reduction and denitrifying species relative to synthetic fertilizer (Yang et al., 2022). However, when manure has been processed to AD and the viscosity has thus been reduced, fewer anaerobic microsites might contribute to a reduction in N_2O emission relative to farmyard manure (Möller, 2015). Thus, manure also affects microbes involved in nitrification and denitrification by altering soil properties that affect microbial activity, such as, soil aeration, pH, moisture, and temperature. Long-term excessive application of synthetic ammonium-based N fertilizers has been a major cause of soil acidification in agricultural land. The effect of livestock manure on soil acidity is quite variable depending on the biochemical composition and frequency of application. Manure has sometimes been shown to cause a decrease in soil pH due to nitrification of ammonium. However, in long term application of manure an increase in pH can also be achieved due to the presence of ions such calcium, magnesium, and compounds such as calcium carbonate in the manure. Changes in soil acidity in turn, result in changing in the soil microbial community structure. In general, fungi are less sensitive to acidic conditions than bacteria; a phenomenon that could cause a shift in the contribution of these communities to microbial processes. When the soil is acidified, N_2O -producing fungal species are more abundant. These conditions inhibit the activity of bacterial denitrifying reductases, which reduces the contribution of bacteria to N_2O emission (Arikan et al., 2009). Moreover, enriching the soil with organic matter through manure decreases the bulk density and improves soil aeration. Aeration is important in nitrification, and it is therefore no surprise that manure treated soil has been associated with greater rates of nitrification. Indeed, manure functions as a direct food source that increases microbial abundance by altering soil conditions so that they become favorable toward certain species of organisms.

Soil borne pathogens and antibiotic resistant genes

In addition to its effect on beneficial organisms, manure also plays a role in controlling soil borne pathogens. Various disease-causing pathogens which initially reside in intestinal tract of livestock include bacteria, fungi, viruses, nematodes, and protozoa are commonly present in manure. The abundance of these pathogens in manure depends on the animal species, the health of the animal, feed type, and antimicrobial additives in feed and prophylactics. During manure handling and application these pathogens can spread and become a pest to plants and cause diseases in animals and humans. Suppressing these pathogens is thus of utmost importance for animal, plant, soil, and human health. Bacteria, which have been found in manure and linked to outbreaks of human illness include *Escherichia coli*, *Salmonella* and *Campylobacter*. These organisms may transfer virulence factors through plasmids. Commonly associated with untreated manure these pathogens can then be transferred to crops consumed by humans. Pathogens may also end up in ground- and surface water through leaching and runoff after manure is land applied. In addition to pathogens, infected animals, might also excrete prions in their feces. Prions are proteins that cause the abnormal folding of proteins in the affected organism. During storage and treatment of manure pathogens and prions can be greatly reduced. Pre-application of manure treatments that include drying, heating, and the exposure to UV light have been shown to have a negative impact on pathogen density. Certain prions, however, might be able to survive extreme temperatures. Upon land application the duration of the survival of pathogens in manure depends on the environmental conditions pathogens are exposed to such as soil type, pH, moisture, temperature, aeration, UV radiation from sunlight, and competition with other organisms. Jiang et al. (2002) postulated that *E. coli* O157:H7 can survive in manure amended soil for extended periods of time even under dry conditions. Although there is thus a risk for the transfer of pathogens to the environment in manure amended soils, manure may, as previously noted, increase the abundance of native microorganisms in soil which will compete with the invasive pathogens for the same space, energy, and food resources. It is well documented that manure can suppress disease causing pathogens in soil by enhancing the activity and abundance of pathogen antagonistic microorganisms who eventually could outcompete the pathogens. The disease suppressing traits of manure can also be attributed to the effect on soil physicochemical properties such as SOM, pH, EC, nutrient availability, and soil water holding capacity which may favor the non-pathogens over pathogenic microbes. In a study evaluating 'Early Dying' in potato, composted beef manure significantly reduced disease incidence and increased potato yield relative to green manure and chemical treatment (Molina et al., 2014). Although manure can control soil borne pathogens and therefore benefit, plant, animal, and human health, it also contains a serious threat to human health in the form of antibiotic resistant genes (ARGs).

ARGs are genetic modifications that microbial organisms develop in resistance against antibiotics. These ARGs are transferrable between microorganisms in the environment and those in humans thus forming a serious threat to human health. Antibiotics used in livestock farming can produce ARGs in the animal which are then introduced to soil upon manure application. Indeed, antibiotic resistant bacteria (ARBs) and ARGs have become soil pollutants of significant concern. Manure amended soil has been associated with an increased abundance of ARGs, a phenomenon that is further enhanced by the ability of manure to increase the abundance of native soil microorganisms that may already carry ARGs. In fact, studies have shown that long term manure application significantly enhanced the abundance and diversity of ARGs in soil, in contrast with synthetic fertilizer which only shifted the microbial community structure without any significant impact on the abundance of ARGs (Wang et al., 2020).

Summary

Although manure has been used as a soil amendment since early civilization, the knowledge of its effect on soil microbes is its infancy. Manure application can improve and alter various soil biological characteristics including microbial abundance and diversity which in turn may restore some lost ecosystem functions. The degree of these effects, however, depends on many factors including manure composition, manure management, weather conditions, soil characteristics, and their complex interaction with each other. Moreover, the rich diversity of organisms in soil presents a wide range of metabolic and environmental needs, which means that manure with its soil altering properties will have different effects on the many species of organisms. Despite its many beneficial impacts, caution must be exercised when considering the use of manure as a fertilizer or soil amendment since improper handling, treatment and application of manure may release pathogens, excess nutrients, and greenhouse gasses into the environment. Various treatment methods including composting and anaerobic digestion among others have been shown to reduce some of these negative impacts. Despite the appearance of the insurmountable complexity of manure, its management, and interaction with the soil microbiome it is evident that manure has many properties, that benefit soil and the organisms in it. Continued development of handling, treatment, and application methods and technologies are therefore necessary if we are to maximize the benefits and minimize the drawbacks of manure to the soil environment.

Abstract

On-site – mainly septic systems – and centralized wastewater treatment systems treat vast volumes daily. Most wastewater from septic systems reaches soils via covered leaching beds. Municipal biosolids are applied to cropland for their nutrient value after receiving treatments of various intensity but the soil is relied on to act as a treatment medium by adsorbing and degrading contaminants, inactivating viruses, and reducing viability of other pathogens. The efficacy of soil treatment depends on climate, hydraulic loading which is managed to induce fast or slow infiltration, the hydraulic properties of the soil, and the functional state of the soil biology.

Key points

- Wastewater must undergo treatment to reduce Biochemical Oxygen Demand as well as the chemical and microbial contaminant loads
- Sewage biosolids, the product of wastewater treatment, can nevertheless carry contaminants and harbor microbial pathogens
- After land application, soil can act as a waste treatment medium, and the treatment's efficacy depends on the soils' hydrological, physical and biological functional parameters and the waste loading rate
- There are three major land-treatment processes: slow rate, rapid infiltration, and overland flow.
- Chemical contaminants, inorganic and organic, can be filtered, adsorbed, precipitated, volatilized, and degraded

- Transport through soil of microbial contaminants can be delayed due to filtration and adsorption
- Unfavorable abiotic and biotic conditions in the soil can inactivate or kill microbial contaminants

Introduction

The application to land of human wastes has been practiced for centuries. The benefit of the nutrients provided in these wastes has been recognized as a major benefit in crop production. However, because of the presence of pathogenic organisms in such wastes, the use of untreated wastes is no longer practiced in developed countries. The main sources are decentralized or on-site wastewater treatment systems (e.g., septic tanks) and wastewater treatment effluents and treated sewage sludges (biosolids).

Decentralized wastewater treatment systems

Decentralized or on-site wastewater treatment systems serve an estimated 21.7 million families in the USA plus numerous business and recreational facilities (U.S. EPA, 2021). Worldwide, septic systems are the means by which 24% of waste water is treated (UN Habitat and WHO, 2021). The basic treatment system comprises a septic tank coupled to a distribution system that spreads the effluent below the soil surface via perforated pipes, the leaching bed. The pipes are surrounded by gravel in an absorption trench, below which is a sand bed on top of the underlying soil. As the wastewater moves from the gravel into the sand, some solids are filtered out and this process continues throughout the passage of the sand bed. A bacterial biofilm forms at the gravel-sand interface, which is responsible for removing organic material from the wastewater together with some minerals. This is an aerobic zone, allowing fast breakdown of organic material. Between 50% and 90% of the waste treatment takes place in the soil.

Newer systems employ a variety of treatment processes including aeration, filtration, clarification and disinfection. The aeration system adds a compartment where the material from the tank is subjected to air that is bubbled through. A filtration unit requires an additional compartment that is filled with natural or manufactured materials in which bacterial films, developed under aerobic conditions, breakdown the organic matter. A newer system involves the use of pumps that slowly draw the wastewater through fiber membranes. Each fiber has billions of microscopic pores that are small enough to prevent suspended solids, bacteria and viruses from passing through. Clarification, which increases the settling out of particulates, requires the presence of additional settling compartments or the addition of surfaces that will encourage adsorption. Disinfection relies mainly on the applying of compounds that release chlorine.

Septic tanks typically need to be pumped out, periodically. Many jurisdictions require the resulting septage to be handled through wastewater treatment plants but some still allow untreated material to be applied directly to land.

Wastewater treatment plants

There are nearly 24,000 wastewater treatment plants in Europe, over 16,000 in the USA and approximately 58,500 worldwide. Those in the USA treat about 150×10^9 L day⁻¹ of wastewater per day (U.S. EPA, 1997) but worldwide the total wastewater produced is approximately 3.6×10^{14} L year⁻¹, of which only 4.1×10^{12} L year⁻¹ go to a treatment plant (Ehalt Macedo et al., 2022). There are typically three treatment stages of piped sewage.

Primary wastewater treatment

Sewage and other waste streams entering a wastewater treatment plant passes through a screen to remove large floating objects, such as sticks, plastics (including wipes) and rags, before entering a grit chamber that allows small metal items, stones, sand-sized mineral particles, coffee grinds and eggshells to settle out. The remaining entrained solids are removed from the sewage in sedimentation tanks. These long narrow tanks hold the wastewater for approximately two hours to allow settling to take place under gravity. The material that settles (known as raw or primary sludge) is removed by mechanical scrapers, which can also remove floating material, such as fats.

The initial treatment involving further time in even slower movement of the wastewater to allow more solids to settle out, leaving only particles less than 10 µm still in suspension. The net effect is to reduce the level of oxygen required by the bacteria that breakdown the organic matter (biological oxygen demand) by a minimum of 20% before entering the next stage of treatment.

Secondary wastewater treatment

At this stage, the process of treating wastewater generally involves biological treatment together with further activities to remove at least 75% of the initial Chemical Oxygen Demand (COD). The trickling filter and the activated sludge processes are the most commonly used secondary treatments.

Trickling filter

A trickling filter is essentially a tank filled with porous media such as a deep bed of stones or slag or purposely designed porous plastic media. The stone beds are commonly up to 2.4 m deep but usually of large diameters, up to 60 m, while the plastic media is usually packed in towers that are tall (up to 12 m), but narrower (6–12 m in diameter). The plastic media can be designed to create crossflow, which has been shown to minimize clogging. The wastewater from the first treatment is continuously trickled over the top of the trickling filter from revolving arms and percolates to the bottom, where it is collected for further treatment. During this process, bacteria gather and multiply on surfaces of the filter material, creating biofilms. Because of this, the process may be also described as biofilm filtration. The steady unsaturated flow of dissolved and fine particulate organic matter entrained in the wastewater allows the bacteria to absorb the organics, thus lowering the biochemical oxygen demand (BOD) of the sewage. Air moving through the spaces between the filter's surfaces provides sufficient oxygen to meet the oxygen requirements for microbial metabolism. Two or more trickling filters may be connected in series so that wastewater can be recirculated for greater treatment efficiency.

Passage through settling tanks, secondary clarifiers, follow the trickling filters to collect the bacteria and their extracellular polymeric substances that are displaced by the flow of wastewater, including sloughed off biofilms.

Activated sludge

Activated sludge treatment consists of an aeration tank followed by a secondary clarifier tank. Wastewater that has passed through the secondary process is mixed with fresh sludge from the secondary clarifier in an aeration tank. Compressed air is then injected into the mixture from the bottom of the tank. As the bubbles rise to the surface of the wastewater the diffused air provides oxygen and a rapid mixing action. Alternatively, aeration can also be supplied by the stirring action of propeller mixing-blades at the surface. The duration of the initial part of the process, about six hours, allows for the production of microbes and the removal of the dissolved organic material. Secondary settling tanks deal with the removal of microbial waste from the process.

Tertiary wastewater treatment

Tertiary treatment allows for a reduction in the level of contaminants, such as key plant nutrients, nitrogen and phosphorus, where effluent is released into lakes or rivers.

Treatments for nitrogen and phosphorous

Oxidation ponds, also known as stabilization ponds, can be used to improve the quality of wastewater effluent through the interaction of sunlight, bacteria, and algae. They are large, shallow ponds or lagoons containing algae. Algal growth depends on photosynthesis using energy from the sun, to fix the carbon dioxide, nitrate and phosphorus released by bacteria in the different treatment stages. During photosynthesis, the algae release oxygen that is required by aerobic bacteria. Mechanical aerators are sometimes installed to supply yet more oxygen, thereby reducing the required size of the pond. Sludge deposits in the pond must eventually be removed by dredging. Algae remaining in the pond effluent can be removed by filtration or by a combination of chemical treatment and settling.

Rotating biological contactors consist of a series of large plastic blocks or disks mounted on a horizontal shaft. The units are partially submerged and thus as they rotate, the biofilms formed on their surfaces are alternatively exposed to anoxic conditions in the wastewater effluent, when they are partially submerged, or are well aerated when lifted above the liquid. During the latter stage, bacteria on the surface of the units oxidize ammonia to nitrite and nitrate but during the anoxic phase, these oxides of nitrogen can be reduced back to ammonia or to dinitrogen gas.

Land application of sewage biosolids

Biosolids from municipal wastewater treatment plants are commonly applied to agricultural land but this is usually subject to regulatory control. After general screening and grit removal, suspended organic material is separated out by sedimentation (Primary Treatment) and the microorganisms present in the waste digest the easily metabolized fraction (Secondary Treatment). In addition, inorganic nitrogen (N) and phosphorus (P) in solution may be removed (Tertiary Treatment). The material is stabilized in a final treatment stage. In this stage the material is subjected to heating and drying, alkaline stabilization to increase the pH, aerobic or anaerobic digestion together with heating, or composting. Stabilization is intended to reduce or eliminate pathogens and make the material less attractive to scavengers after land application. During these different treatment stages, the microbes in sewage are reduced in number, becoming concentrated in the sludge. However, some pathogens are still present in the effluent.

Biosolids are applied to land, either as a liquid or, if they undergo dewatering before being spread, as a cake. These materials are commonly referred to as municipal or sewage biosolids.

The projected production of sewage biosolids for 2010 in the USA and the original 15 countries of the European Union was about 16 Tg dry matter per year (Epstein, 2002). Although not all European countries use sewage sludge in agriculture, over the period 1996–1998 France applied 60% of its production to agricultural land and comparable values for Spain and the UK are 46%, Germany 40% and Italy 16%. Typically, between 50% and 70% of sewage biosolids produced are land applied (Epstein, 2002). Kelessidis and Stasinakis (2012) provide a comparative assessment of treatments and approaches to the disposal of sewage biosolids in Europe.

Land application of effluent from wastewater treatment plant

Land treatment is defined as the controlled application of wastewater onto the land surface to achieve a planned degree of treatment through natural physical, chemical, and biological processes within the plant–soil–water matrix. During land treatment of wastewater effluents, biological and chemical pollutants are removed by physical (settling, filtration), chemical (adsorption, precipitation), and biological (e.g., plant uptake, microbial transformation) processes. The key objectives of land application of wastewater are further effluent treatment, groundwater recharge, and provision of nutrients for agricultural crops. However, effluent is used in many water-short areas of the United States, with or without disinfection, for crop and landscape irrigation.

There are three major land-treatment processes: slow rate, rapid infiltration, and overland flow (Fig. 1, Table 1). A comparison of the design features of these land-treatment systems are seen as important in the recharge of drinking-water aquifers, and slow-rate systems as a means of crop production in the arid regions of the world. Because of the potential impact of contaminants on underground drinking-water supplies, the fate of trace organics and pathogens have received increasing attention where rapid infiltration is used to supplement groundwater supplies. Because of the transport of food crops around the world today, the fate of pathogens in slow-rate systems has also received more attention.

An expert review of the epidemiological evidence, sponsored by the World Health Organization, recommendation that treated wastewater contain less than one viable intestinal nematode egg L^{-1} (arithmetic mean) for restricted or nonrestricted irrigation, and less than 10,000 fecal coliform bacteria (FC) L^{-1} (geometric mean) for unrestricted irrigation (Blumenthal et al., 2000).

Fig. 1 (A) Slow-rate irrigation system; (B) overland-flow system; (C) rapid-infiltration system. Reproduced from the US Environmental Protection Agency (1981) *Technology Transfer Process Design Manual for Land Treatment of Municipal Wastewater*. EPA/1-81-013. Cincinnati, OH: USEPA.

Table 1 General characteristics of the three methods used for land application of sewage effluent.

Factor	Application method		
	Low-rate irrigation	Overland flow	High-rate infiltration
Main objectives	Reuse of nutrients and water Wastewater treatment	Wastewater treatment	Wastewater treatment Groundwater recharge
Soil permeability	Moderate (sandy to clay soils)	Slow (clay soils)	Rapid (sandy soils)
Need for vegetation	Required	Required	Optional
Loading rate	1.3–10 cm week ⁻¹	5–14 cm week ⁻¹	>50 cm
Application technique	Spray, surface	Usually spray	Surface flooding
Land required for flow of 10 ⁶ L day ⁻¹	8–66 ha	5–16 ha	0.25–7 ha
Required depth to groundwater	Approx. 2 m	Undetermined	5 m or more
BOD and suspended solid removal	90–99%	90–99%	90–99%
N removal	85–90%	70–90%	0–80%
P removal	80–90%	50–60%	75–90%

BOD, Biochemical oxygen demand.

Land-treatment systems are capable of reducing the levels of pathogenic microorganisms, biochemical oxygen demand (BOD), suspended solids, nutrients (N and P), toxic metals, and trace organics. Suspended solids are removed by filtration and sedimentation. Soluble organics are removed by microbial action in the soil. Nitrogen is removed by sedimentation-filtration (e.g., particle-associated organic nitrogen), adsorption to soil, volatilization, e.g., ammonia (NH₃), uptake by crops, and biological denitrification. Adsorption to soil particles, chemical precipitation, and uptake by vegetation combine to remove P.

Types of land-treatment processes

Slow-rate process

Slow-rate irrigation systems are the most frequently used land-treatment system. There are approximately 1200 systems in the USA. Slow-rate land treatment is the application of wastewater to a vegetated land surface, with the applied wastewater being treated as it flows through the plant–soil matrix. Some of the flow percolates to the groundwater and some is used by the vegetation. Off-site surface runoff of the applied wastewater is generally avoided in the design. Nitrogen is often the limiting factor in these systems because of strict standards for levels of nitrate in drinking water. In arid lands, salts at acceptable levels for crop production also may be limiting. Usually, sandy loams or clay loams are the preferred soil type.

In slow-rate systems, the soil can be as shallow as 0.3 m for grass crops, but 1.5 m is preferred for complete wastewater treatment. Retention of contaminants is a function of residence time of the wastewater in the soil and the degree of contact with the soil colloids.

BOD in most slow-rate treatment systems is applied at rates of less than 11 kg ha⁻¹ day⁻¹, which is an order of magnitude smaller than the capacity of the soil. High-strength food-processing wastewater systems are loaded as high as 9500 kg ha⁻¹ day⁻¹. The BOD reductions in most systems exceed 98%. Filtration through the soil results in removal of 99% or more of total suspended solids.

Nitrogen removal is achieved using a nitrogen balance that matches the expected removal plus a percolate nitrate-N of less than 10 mg L⁻¹, which is the drinking-water standard in the USA. Slow-rate systems use forage crops to remove much of the applied N. To achieve the nitrogen uptake rates expected for the crop, excess nitrogen must be applied so that the crop can compete effectively with soil microorganisms for the available nitrogen. Biological-N removal occurs by nitrification–denitrification. The loss by denitrification depends on the ratio of BOD-to-N and the soil temperature, pH, and moisture content. Intermittent application, which is characteristic of slow-rate systems, serves to enhance nitrification followed by denitrification. Ammonia volatilization losses of 10% can be expected if the soil pH is greater than 7.8 and the cation exchange capacity is low (little adsorption of ammonium by the soil). For soils with less than 2% organic matter, storage of N in the soil can be a significant loss for the first 3–4 years of operation of the system. Eventually, equilibrium is reached and the net storage of N stops.

Removal of P depends mainly on the formation of insoluble phosphates with metals at the soil surface. It is generally found that about 98–99% of P is removed in this way.

The concern with pathogens in slow-rate systems is related to their potential for reaching the groundwater, contamination of adjacent surface waters, or contamination of the crop. The small application rates used for wastewater generally limits the potential for groundwater contamination, and contamination of surface waters can be controlled by proper management and site selection. However, enteric viruses have been detected in groundwater beneath slow-rate systems when high rates of wastewater are applied to areas with shallow water tables. Food-crop contamination with pathogens easily occurs during furrow irrigation, but can be limited by drip irrigation and covering the soil surface with plastic sheeting.

Rapid-infiltration process

In rapid infiltration, most of the applied wastewater percolates through the soil and the treated effluent seeps through to the groundwater, where it may be collected in recovery wells for drinking water or irrigation. The wastewater is applied intermittently at

high loading rates ($6\text{--}125\text{ m year}^{-1}$) onto a permeable soil (e.g., sands or loamy sands). Application is usually in basins and vegetation is usually not planted. Recovery wells may be used to reclaim the treated water for irrigation or as a drinking-water source. The treatment potential of rapid-infiltration systems is less than in slow-rate systems. Removal of N is generally small but may be enhanced by encouraging denitrification. Denitrification requires adequate carbon (as found in primary wastewater effluents) and low oxygen levels, necessitating flooding periods as long as 9 days, followed by drying periods of approximately 2 weeks. Climate and season will affect the intervals of flooding and drying due to their influence on microbial activity.

Typical BOD loadings for rapid-infiltration systems using municipal wastewater range from 27 to $175\text{ kg ha}^{-1}\text{ day}^{-1}$ with removals ranging from 74% to 96%. BOD loadings of industrial systems range from 112 to $676\text{ kg ha}^{-1}\text{ day}^{-1}$. Suspended-solids loadings greater than $112\text{ kg ha}^{-1}\text{ day}^{-1}$ require more frequent diskings or scarifying of the infiltration basin surface to avoid plugging of the soil.

Nitrification–denitrification is the principal mechanism of ammonia (NH_3) and N removal from wastewater in rapid-infiltration systems. Ammonia adsorption of NH_3 also plays an important role in retaining ammonia in the soil long enough for biological conversion. Nitrification and denitrification are affected by temperature and the amount of organic carbon available. It has been found that nitrification rates of up to $67\text{ kg ha}^{-1}\text{ day}^{-1}$ can be achieved under favorable moisture and temperature conditions. Removal of N is a function of detention time, BOD-to-N ratio, and anoxic conditions. Detention time is related to hydraulic loading rates through the soil profile and the soil type dependent hydraulic conductivity. For effective nitrogen removal (80% or more), the loading rate should not exceed 3–4 cm. The BOD-to-N ratio needs to be 3:1 or more to ensure adequate carbon to drive the denitrification reaction. Secondary wastewater effluent will have a BOD-to-N ratio of approximately 1:1, whereas primary effluent usually has a BOD-to-N ratio of 3:1. To overcome the small ratio of BOD-to-N in secondary effluent, a longer period of application (7–9 days) is necessary. Typical removal of total nitrogen ranges from 38% to 93%.

Adsorption and chemical precipitation contribute to P removal. The adsorption occurs quickly and the chemical precipitation occurs more slowly; removal typically ranges from 40% to 97%.

Removal of bacteria, helminths, and protozoan parasites is largely accomplished by filtration. Under unsaturated conditions almost all are removed within a meter of the soil surface. Virus removal is dependent upon adsorption to the soil surface; viruses have the potential to travel long distances under the right conditions (50 m or more). The depth of the unsaturated or vadose zone is important in the degree of removal of viruses before the wastewater reaches the aquifer. Expected removals of virus should be 99% or more.

Overland-flow process

In overland-flow treatment, wastewater is applied at the upper reaches of grass-covered slopes of 2–10% grade and allowed to flow over the vegetated surface into runoff collection ditches. Typical slopes are 2–4% in grade and 36–45 m long. The overland-flow process is best suited to sites having relatively impermeable soils. The most suitable soils are clay or clay-loamy soils with a permeability equal to or less than 0.5 cm h^{-1} . The wastewater is treated by a thin biofilm and plants as it flows down the slope. Removal of nitrogen is due to nitrification followed by denitrification, and uptake by the grass or other plants. Phosphorus removal is via adsorption and precipitation.

In municipal systems, the BOD loading rate typically ranges from 12.3 to 4 kg ha^{-1} . Biological oxidation accounts for the 90–95% removal of BOD normally found in overland-flow systems. A typical BOD concentration in treated runoff water is approximately 10 mg L^{-1} . Overland flow is effective in removing most suspended solids, with effluent total suspended solids between 10 and 15 mg L^{-1} .

The removal of nitrogen depends on nitrification–denitrification and the crop uptake of nitrogen. Denitrification can account for 60–90% of the nitrogen removed, with denitrification rates of 160 kg ha^{-1} . Phosphorus removal in overland-flow systems is limited to approximately 40–50% because of the lack of soil–wastewater contact.

Overland flow is not very effective in removing microorganisms. Fecal coliforms can be reduced by approximately 90% when raw or primary effluent is applied; however, minimal removal occurs when secondary effluents are applied. Enteric virus removals of up to 85% have been observed with overland flow.

Treatment mechanisms

In the land application of wastewater, the soil is used as a treatment medium. Some substances pass through the soil and into the groundwater, some are utilized by growing plants, while others are retained almost indefinitely within the soil. Proper design of land-application facilities must relate the fate of pollutants to the properties of soil with which they may interact and minimize the fraction of contaminants passing through to groundwater. There are several separate-unit processes that can be adopted for removal of suspended solids, total dissolved solids, biochemical oxygen demand, nitrogen, phosphorus, and toxic substances. Waste-treatment mechanisms that occur in soils can conveniently be categorized as physical, chemical, and biological. Within each category, various processes act to remove or alter specific pollutants.

Filtration

As wastewater moves into and through soil pores, suspended solids are removed by mechanical filtration. The actual depth at which removal occurs varies with the size of suspended particles, soil texture, and the rate of application. The larger the hydraulic loading rate and the coarser the soil, the less the detention rate, and thus the greater the distance required. However, when loading rates are

such that much of the applied water is held in the soil, additional removal can occur as suspended materials settle or adhere to the surfaces of the soil particles. Some organic particles and some organisms such as worms and protozoa are large enough so that removal by simple blockage occurs. Both bacteria and viruses, however, are small enough that they can move through the soil pores. While filtration in the soil matrix limits the movement of most bacteria to a meter or less, viruses are too small to be affected, and filtration is not believed to play a significant role in their removal. In practice an organic mat or 'Schmutzdecke' forms at the soil surface, enhancing the removal of particulates. Suspended matter can evidently clog soil pores and thereby severely reduce the infiltration rate. In rapid-infiltration operations, flooding and drying cycles help restore infiltration rates. During flooding the infiltration rate is reduced over time. Drying of the Schmutzdecke results in its cracking and removal during the next infiltration event.

Adsorption and precipitation

Chemical reactions among dissolved ions or compounds and interactions with the soil solid-phase alter the mobility of waste pollutants. Some dissolved constituents are retained within the profile indefinitely, whereas the movement of others is only temporarily restricted or unaffected. Two processes, adsorption and precipitation, account for most of the retention. Adsorption refers to the net effect of interactions between dissolved and particulate (i.e., viruses) matter of the soil and humus particles. Precipitation is the formation of an insoluble form of a substance that was originally in solution. Ion exchange is one type of adsorption process. Anion exchange is of very minor importance in land-application systems. Phosphorus is the only anion appreciably retained in soils, though the primary mechanism is not anion exchange. The predominant ion exchange reactions in most soils involve cations and are related to the cation exchange capacity. In wastewater-treatment systems, the retention of dissolved cations depends largely on their concentration in solution entering the soil. Large concentrations overcome a higher degree of attraction of other cations toward the soil matrix. Many of the heavy metal cations such as zinc, copper, nickel, cadmium, mercury, lead, and chromium are present in wastewater at concentrations too low to be appreciably affected by cation exchange reactions. These cations seem to be incorporated into the soil solid-phase in a nonexchangeable form.

Chemical reactions

Phosphorus and nitrogen are at least partially controlled by chemical mechanisms in the soil. The most important chemical mechanism for nitrogen removal is the reaction of positively charged ammonium ions with the soil cation-exchange complex.

Volatilization

Volatilization refers to the evaporation of chemical vapor from soil or water and its subsequent loss to the atmosphere. Many organic compounds are volatile in water, as are some nitrogen compounds, such as ammonium (NH_4^+) and nitrous oxide (N_2O) generated from biological transformations. In addition, some inorganic chemicals (e.g., selenium compounds) may be rendered volatile through biological reactions. For a given chemical, the extent of volatilization is very dependent on the soil and atmospheric conditions. In general, volatilization is greatly reduced in soil compared with water, because the soil solid-phase retains the chemical mass, thereby reducing its vapor pressure. In addition, the soil can offer substantial resistance to the transport of the chemical from the soil profile to the surface, particularly if the soil is wet and little upward flow of water is occurring. In rapid-infiltration processes where the wastewater is ponded over the surface for prolonged periods of time, the primary route of volatilization loss is from the surface of the standing water. During the drainage cycle, when the soil becomes unsaturated, volatile constituents in solution near the surface can evaporate and escape to the atmosphere.

Ammonia present in wastewater is very volatile and vaporizes from the anhydrous form immediately upon exposure to air. When soil-water content is high and a source of organic carbon is present nitrite may be transformed anaerobically by biological denitrification to several gas species (primarily N_2O and N_2).

Biological mechanisms

Soil microorganisms alter the waste constituents through organic matter decomposition, inorganic transformations, and nutrient assimilation. These processes are largely restricted to the upper meter of soil. The ability of soil microorganisms to decompose organic matter is a function of their population complexity. The functional diversity of microbial communities enhances the capability of soil to degrade a wide variety of organic substances; some microorganisms prey on pathogenic bacteria and reduce the survival of viruses. The rate at which organic matter decomposition occurs and the exact nature of the intermediate and end products depend in part on the composition of the added organic matter in the wastewater. Soil factors, however, exert considerable control as well. The presence or absence of oxygen, more than any other single factor, determines the rate and end products. The oxygen status of the soil is a function of soil porosity, and properties that favor rapid transmission of water also favor oxygen movement unless the soil is completely saturated.

Decomposition proceeds most rapidly under aerobic conditions. Under aerobic conditions, up to 60% of the organic carbon may be respired by organisms as carbon dioxide in the initial stage of decomposition. Much of the rest is incorporated into microbial cells, and some of this is subsequently respired when the population declines. Through organic matter decomposition, N, P, sulfur (S), and a host of other trace elements are converted from organic to inorganic forms, i.e., mineralization. Many of the elements that are mineralized during organic matter decomposition are then subject to inorganic transformation in the soil and are assimilated by plants in overland-flow and irrigation-treatment systems. Vegetation thus functions as a sink where waste nutrients, most notably nitrogen and phosphorus, can be effectively immobilized. When harvested, vegetation plays an integral part in the renovation or 'treatment' of the applied wastewater.

Fate of specific contaminants

Metals and trace elements

Factors that affect the retention of trace elements by soils include soil texture, pH, soil organic matter, and contents of amorphous oxides of Fe, Al, and Mn. Most soils have a high capacity to attenuate the concentration of copper and lead. The retention of other trace elements is best correlated with the clay content of free iron oxides of the soil. Capacities for attenuating cationic elements (Cu, Pb, Be, Zn, Cd, Ni, and Hg) in soils tends to increase with their clay and iron oxide contents. For anionic trace elements (SeO_3 , VO_3 , AsO_4 , CrO_4), retention in the soil also increases with increasing clay and iron oxide content of the soils. In general, the solubility of the cationic trace-element species increases as the pH of the soil decreases. By contrast, the solubilities of anionic trace-element species in the soil tend to increase with the pH of the soil.

Metals and trace elements may be removed by a number of mechanisms during land application of wastewater. Those associated with suspended matter are retained at or near the soil surface. In rapid-infiltration systems, they accumulate in the colloid material in the surface-clogging layer, which eventually must be removed to restore infiltration. Smaller suspended particulates that can move through soil pores without becoming trapped are also attenuated by sorption to mineral surfaces in the soil matrix. For dissolved elements, ion exchange, precipitation, surface adsorption, and complexing with organic compounds are important. The principal mechanisms that immobilize dissolved trace elements in the wastewater within the soil appear to be absorption and precipitation. Most soils appear to have a high capacity to remove trace elements during land treatment of wastewater. The amounts of trace elements removed by crops are small compared with the amounts applied to the soils though application of wastewater (Table 2).

Because soil sorption may be finite for most trace elements, there may be long-term accumulation of metals in the soil. Groundwater concentrations of silver, barium, cadmium, cobalt, and chromium below the rapid-infiltration site at Hollister, California, have been unaffected by the additions of wastewater to the overlying soil. However, manganese, nickel, iron, zinc, lead, and copper are above background levels. Soil samples taken at the Whittier Narrows infiltration facility after more than 20 years of operation have shown elevated levels of cadmium, chromium, copper, nickel, lead, and zinc in the top 60 cm, but not below that depth, suggesting that the soil has the capacity to remove metals for many more years of operation before groundwater is affected.

Organic compounds

Organic compounds vary greatly in their mobility, volatility, and persistence in soil. In land-application systems, volatile compounds volatilize prior to application, and only soluble organic compounds enter the soil. The fate of the soluble compound depends on the degree to which it is chemically or biologically transformed during its passage through the system. Organic compounds degrade by hydrolysis, photo-decomposition, or redox reactions. Microbial conversion occurs chiefly at or near the soil surface, where bacterial populations and organic carbon levels are greatest. Low organic carbon levels limit microbial action in the deeper regions of the vadose zone during treatment in rapid-infiltration systems. The travel-time of an organic compound may be roughly estimated by its retardation factor in a given soil. The overall action of the chemical and microbiological processes transforming an organic compound moving through the soil may be crudely expressed as the half-life or degradation rate constant. The duration of the half-life compared with the travel-time can be used as an index of the potential for the compound to survive its contact and passage through the soil.

The dissolved organic carbon (DOC) in domestic, secondary-treated wastewater during rapid infiltration is reduced by 50% after passage of a few meters through the soil. DOC is primarily removed by microbial action during passage through the soil, with more than half being removed during passage through the top 8 cm of soil. With long residence times in the soil, aquifer DOC is reduced to 1 mg L^{-1} after 12–24 months.

Disinfection by-products

In most cases, wastewater is disinfected before land application with chlorine, chloramine, ozone, or ultraviolet light. In the case of chemical oxidizers, this results in the formation of disinfection by-products which may potentially be harmful to human health.

Table 2 Expected trace element removal by vegetation from wastewater-irrigated soils.

Element	Typical concentration in wastewater (g L^{-1})	Annual input (g ha^{-1})	Typical concentration in vegetation (g g^{-1})	Annual removal (g ha^{-1})	Removal (%)
As	<0.005	<60	1	5	8.3
Cd	0.005	60	0.5	2.5	4.2
Cr	0.025	300	0.5	2.5	0.8
Cu	0.10	1200	15	75	6.3
Hg	0.0009	11	0.02	0.1	0.9
Pb	0.05	600	2	10	1.7
Zn	0.15	1800	50	250	13.9

At an application rate of 1.2 m year^{-1} . Assuming annual dry matter yield of 5 t ha^{-1} e.g., potatoes.

Some of these compounds are listed in Table 3 along with their probable fate during land application of wastewater. In addition to known disinfection by-products, residual halogen is present when chlorine is used. This material may then appear as adsorbable organic halogen (AOX). Sorption processes do not play a significant role in their removal. Under anoxic conditions removal is probably based on co-metabolism and is related to the DOC that is needed as a substrate. Ozone disinfection of wastewater improves the biodegradability of refractory organic compounds and co-substrate concentration for AOX co-metabolism in soil columns. AOX removal in 1-m soil columns to which secondary effluent is applied averages 30%.

Endocrine disruptors

Many endocrine-disrupting compounds are present in wastewater at trace quantities (i.e., estrogens, pesticides, polychlorinated biphenyls, phthalates, pharmaceuticals). Estrogens are probably the largest contributors to the endocrine-disruption activity in domestic wastewater, since daily urination adds estrogen to household wastewater. Humans are known to excrete between 10,000 and 100,000 ng L⁻¹ of 17 β -estradiol per day. Synthetic estrogens such as 17 α -ethinyl estradiol have been detected in wastewater and in surface waters affected by effluent discharge. Measurements of endocrine-disrupting compounds displaced by a fluorescent estrogen assay or cell proliferation assay have shown the reduction of endocrine disruptors during rapid infiltration. By cell proliferation assay, the estradiol equivalent value of 71 ng L⁻¹ was found to be reduced to 13.7 ng L⁻¹ after passage of 63 m through the vadose zone. The equivalent 17 β -estradiol activity measured by a binding assay was reduced by 97% after travel through the vadose zone to reach the aquifer. Since the study site had been in operation for more than 10 years, it seems unlikely that endocrine disruptors would ever break through the vadose zone.

Pharmaceuticals

There has been increasing concern about the fate of micropollutants originating from pharmaceuticals and active ingredients in personal-care products (e.g., soaps, deodorants) that are introduced into domestic wastewater. There is evidence that substances of pharmaceutical origin are not completely eliminated during wastewater treatment or biodegraded in the environment. At two rapid-infiltration sites in Arizona, neither ibuprofen nor naproxen or any other acidic drug were detected in groundwater wells downgradient of the infiltration basins (Table 4). These results indicate a high potential for degradation of anti-inflammatory and lipid-regulator drugs. However, antiepileptic, carbamazepine, and primidone drugs have been detected in all of the wells, suggesting that they are able to persist in soil-treatment systems.

Microorganisms

From the standpoint of acute diseases, microbial contaminants are of greatest concern during the land application of wastewater. Microorganisms are responsible for more than 90% of all waterborne out- breaks reported each year in the USA. Hundreds of

different types of pathogenic microorganisms (i.e., bacteria, viruses, protozoa, helminths) are excreted in fecal material of infected hosts and these can find their way into municipal wastewater. The number of types of pathogenic microorganisms present in wastewater varies by location and over time at a given location. A variety of factors influence pathogen content of wastewater, including the incidence of the disease in the population, the season of the year, the economic status of the population, and water use patterns. Diseases caused by waterborne organisms range from mild gastroenteritis to severe and life-threatening illness, such as hepatitis, cholera, typhoid, paralysis, meningitis, heart disease. New enteric pathogens are discovered almost yearly and the significance of new ones changes over time. Coronaviruses, which include SARS-CoV-2 which causes COVID-19, do consistently evolve and new variants are routinely identified and may be found in municipal wastewaters. Enteric bacteria are common in wastewaters, and they may pose health risk to wastewater treatment plants workers. Moreover, occasionally small proportions of enteric bacteria might survive treatment and reach farmland where the biosolids are used as nutrient sources. This is why biosolids application to crops that are intended to be used fresh for human consumption is generally regulated to avoid food-borne illnesses.

The resistance of enteric viruses to environmental stresses makes them good indicators of the efficacy of wastewater treatment. If conditions are effective for disinfection of enteric viruses, they are most likely effective for most other viruses and bacteria. Nevertheless, treated biosolids can be re-contaminated during handling and storage, commonly due to direct contact with rodents and wild birds. During land application of wastewater, pathogens are removed from the system by a combination of die-off (inactivation in the case of viruses) and physical filtration or adsorption by the soil or plant material. Pathogen removal by overland flow systems has been little-studied, but it is not expected to result in large reductions of enteric bacteria or viruses. Irrigation systems and rapid-infiltration systems have been studied more because of the potential for crop and aquifers.

Transmission of food-borne illness by enteric pathogens due to irrigation with untreated wastewater has been well-established for more than 100 years. For this reason, irrigation with untreated wastewater for food, crops is usually forbidden. Wastewater to be used for food crop production should meet the same standards as drinking water and be intensely monitored. Thus, almost all irrigation with wastewater is for the production of nonfood crops or fruit crops. However, outbreaks of disease associated with apples and raspberries caused by the parasites *Cryptosporidium* and *Cyclospora* suggest that only wastewater treated to potable standards should be used in any food crop production.

Factors controlling the survival of pathogens are shown in Table 5. Table 6 shows the range of reported survival times of selected enteric pathogens in the environment. Temperature is probably the most important factor controlling persistence of pathogens on plant material and soil. The die-off of pathogens increases as the temperature increases; however, under proper conditions (high humidity), some growth of bacterial pathogens may occur on the plants in the field. Rotavirus and enteroviruses appear to be inactivated very rapidly on irrigated grass under the conditions found in the arid southwestern USA.

Moisture and temperature govern survival of bacteria and inactivation viruses. *Salmonella* and other enteric bacteria can survive for several weeks on grass if sufficient organic matter and moisture is available. Helminth eggs such as *Ascaris* are believed to survive for 30–60 days, although they may survive many months in the soil itself.

Table 5 Factors influencing enteric pathogen survival in soils.

<i>Factor</i>	<i>Comments</i>
Temperature	Lower temperatures promote increased survival
Moisture content	Survival is decreased in drying soils. Increases may result in bacterial growth
pH	Survival is decreased pH extremes
Soil type	Survival influenced by chemical, textural, and mineralogical properties such as pH, exchangeable ion content, and water-retention capacity
Organic matter	Survival enhanced and growth of bacteria possible
Soil microflora	Survival is decreased in nonsterile soil
Salt species and concentration	Cationic type and ionic strength may influence survival
Soil surfaces	Survival may be enhanced by adsorption to soil particles
Saturation	Air–water interface under unsaturated conditions may enhance viral inactivation

Table 6 Survival of pathogens in soils.

<i>Organism</i>	<i>Survival time (days)</i>
Coliforms	38
Fecal streptococci	26–77
<i>Salmonellae</i>	15–90
<i>Salmonella typhi</i>	1–120
<i>Entamoeba histolytica</i> cysts	6–8
Enteroviruses	8–175
<i>Ascaris</i> ova	Up to 2 years

Table 7 Factors influencing microbial transport.

Factor	Comments
Size of microorganism	Transport of bacteria and parasites is limited because of size in most agricultural soils
Adsorption	Major factor in limiting virus transport through soils. Also plays a role in bacterial transport
pH	Lower pH enhances adsorption
Salt species and concentration	Increased cation valency and ion concentration increase retention; low ionic strength promotes desorption and transport
Organic matter	Some organics (e.g., humic and fulvic acids) interfere with adsorption and cause desorption
Metal oxides	Virus adsorption to iron oxides occurs readily in soils
Hydraulic conditions and moisture content	Increase flow rates and saturated flow decrease adsorption

Temperature significantly influences the survival of enteric pathogens in soil. Survival of bacteria in soils is also favored by cold temperatures. However, freeze–thawing increases mortality of enteric bacteria and protozoa. Fluctuating temperatures, even above freezing, also reduce survivability of fecal bacteria, when compared to constant temperature conditions. *Cryptosporidium* may persist in soils for several weeks, although its survival time is reduced at temperatures above 35 °C and if multiple freeze–thaw cycles in the soil take place. Extreme acidic or alkaline conditions (pH <6.0 or >8.0) tend to adversely affect the survival of both enteric bacteria and viruses in soil. Greater moisture also enhances survival of most enteric organisms in soil as does greater concentrations of organic matter in the wastewater.

Direct comparisons suggest that non-enveloped viruses (e.g., poliovirus, rotavirus, coxsackievirus) tend to resist inactivation better than enveloped viruses under environmental stress conditions. Temperature is critical. Poliovirus type one is inactivated at a rate of 0.06 log₁₀ h^{−1} and rotavirus SA-11 at 0.04 log₁₀ h^{−1} during the winter (4–10 °C) in Arizona (USA). The rates of die-off during the summer are 0.37 log₁₀ h^{−1} and 0.2 log₁₀ h^{−1}, respectively. It would appear that 8–10 h is needed during the summer and 16–24 h during the winter before inactivation of these viruses. SARS-CoV-2 survives best at low temperatures: on surfaces median estimated virus half-life was measured at >24 h at 10 °C and 40% RH, but ~1.5 h at 27 °C and 65% RH (Morris et al., 2021). However, in soil, enveloped viruses such as SARS-CoV-2 might survive up to 60 days at 10% moisture (Anand et al., 2021).

Transport of microorganisms through the soil is influenced by many of the same factors that affect survival of microorganisms (Table 7). Because of their relatively large size, bacteria, protozoan parasites, and helminths are usually removed within a meter or less of the soil surface. Because of their small size (20–200 nm), viruses have the potential to travel the greatest distances through soil. Removal largely occurs by adsorption to the soil surface and is influenced by the surface properties of the virus and soil, properties which are also affected by the ionic properties of the soil solution. Electrostatic and hydrophobic interactions control the degree of adsorption. Transport is favored in sandy soils with a low clay content. Adsorption largely occurs near the soil surface because of the presence of iron oxides to which the negatively charged viruses readily adsorb. Transport is more limited under unsaturated conditions and at pH levels greater than 8.0. Organic matter in wastewater reduces adsorption because of competition for adsorption sites on the soil surface.

Abstract

Human activities have caused a rapid climate change affecting all parts of the biosphere, including soils. Soil organisms from all three domains of life, their interactions, and all soil processes for which they are responsible are influenced by and in turn respond to climate change. The understanding of how soil organisms and their processes react to climate changes, is thus central to our ability to manage ecosystems and develop strategies to mitigate climate change. This chapter examines the current state of soil biology (from organisms and communities to the processes they control) in the context of climate change and identifies current gaps in knowledge and promising ways forward.

Key points

- Climate change experiments have many shortfalls in addressing realistic situations, including interactive effects and non-linear behaviors.
- Climate change affects soil biology both directly and indirectly.
- Climate change has large effects on soil communities, but with taxa-specific sensitivities.
- Studying the interactions of soil biota is challenging but represents an important new approach in climate change research in soils.
- Soil organisms are key players for almost any soil process and can potentially cause large feedback to climate change.

Introduction

It is unequivocal that human influence has caused rapid climate change that affects all parts of the biosphere, including soils. Soil temperature and moisture changes are evident in almost all regions of the world influencing the composition and functionality of soil communities. Globally, soils harbor the largest reservoir of organic carbon (around 1500–2400 Gt of carbon in the top meter), and any reduction in soil carbon stocks due to climate change can introduce strong positive feedbacks through increased CO₂ emission into the atmosphere. In contrast, targeted soil carbon management creates opportunities for carbon sequestration and for mitigating climate change.

The magnitude and direction of potential soil feedbacks to climate change depend on soil organisms. For example, both soil organic matter formation and decomposition are mediated by the growth, turnover and carbon use efficiency of soil microorganisms. The respiration by heterotrophic soil organisms is responsible for a CO₂ flux of around 60 Gt C per year from soils to the atmosphere, while autotrophic soil organisms are largely responsible for the production and uptake of the greenhouse gases nitrous oxide and methane. Soil organisms are thus at the very center of understanding the interaction between soil and climate change.

Fig. 1 Climate change affects soil communities, their interaction and soil processes at different levels. Experimental studies often focus on the impacts of single climate change factors, although interactive effects will emerge during co-occurring changes in elevated CO₂, temperature and precipitation. All these factors can either directly affect the physiology, activity and composition of the soil community, or indirectly, via changes of plant inputs and abiotic soil properties. Impacts of climate change on soil biology can be studied at different levels, from single organisms and their interactions up to the processes they control. Effects on soil organisms are challenging to predict given the high biodiversity present in soils, with species from all domains of life interacting with each other. Changes in abundance of soil biota (i.e., in the community composition) and their activity have been recorded, although there is still uncertainty on possible acclimation and adaptation to climate change. Climate change impacts on interactions are difficult to assess given the small scale at which the interactions occur and their high level of dynamicity in space and time, further complicating the prediction of emerging behavior under climate change. Changes at all the investigated levels will contribute to feedback to climate change, by regulating the amount of carbon stored in soil and released to the atmosphere via greenhouse gas emissions.

The inextricable link between climate and soil organisms represents a major scientific challenge. Soil is likely the most biologically diverse system on earth and encompasses taxa from all domains of life: archaea, bacteria, and eukaryotes (including taxa from the phyla fungi, animals, protists and plants), and from viruses (Fig. 1). All these organisms are interacting with each other and with their abiotic environment at various spatial and temporal scales, leading to an unparalleled functional complexity (Fig. 1). Thus, to understand soil, it needs to be considered as an integrated system. Yet, most studies focus on a single group of organisms, largely ignoring their interactions.

Direct versus indirect effects of climate and environmental change

Although most organisms respond directly to temperature or soil moisture, other environmental perturbations have little to no direct effects (Fig. 1). One of the many examples of an environmental perturbation that usually does not directly affect soil organisms, is elevated atmospheric carbon dioxide concentration. First, soil CO₂ levels are usually much higher than atmospheric CO₂ levels and second, most soil organisms are heterotrophic and only fix CO₂ anapleurotically, i.e., they replenish carbon to the metabolism when limited by organic carbon. Yet, CO₂ has a strong indirect effect on many groups of soil organisms: in response to

elevated CO₂ plants may increase biomass production, alters its biochemical composition and change their belowground carbon allocation and leaf litter input, affecting the amount and chemistry of organic carbon available as substrate for the soil food web. However, not only elevated CO₂, but all climate change drivers can cause indirect effects on soil organisms via changes in quality and quantity of plant carbon inputs (Fig. 1). Such indirect effects of climate change may be stronger than the direct ones. Keeping the two factors apart is one of the great challenges when investigating climate change effects on soil biology.

Climate change experiments

Although we are in an era of ongoing climate change, most knowledge on how climate change affects soil and soil organisms comes from climate change experiments. Such experiments are usually short- to medium-term. However, although many indirect effects are manifested only over decades, as for example, those from changes in plant species composition, 15-year studies are already regarded as long-term experiments in most of the scientific literature. In addition, many experiments manipulate only one or two climate change factors at a time. Climate change, however, does not alter only one factor alone. For example, both elevated CO₂ and temperature can cause changing soil moisture conditions, or induce changes in plant water use, thereby modifying the available soil water. Droughts often occur together with heat waves. Hence, predicting climate change effects from single factor experiments is only possible if their impacts on soil organisms were additive, something that, to date, the few multifactorial climate change studies have failed to show convincingly (Rillig et al., 2019).

Interactive effects of more than one co-occurring climate change factor cannot be predicted from studies varying single factors, as this would require a priori knowledge of the response and the interactions of all soil organisms to climate change factors—an impossible task in natural ecosystems. In addition, as climate change factors are often manipulated to a single pre-defined level, many experiments do not allow evaluation of non-linear effects commonly found in many biological systems. For example, soil moisture affects heterotrophic respiration non-linearly, with highest rates found at intermediate soil moisture content. Comparison of climate change experiments and generalization of results are complicated by such non-linear relationships or the interactive effects of different climate change factors. Seemingly contradicting results of climate change experiments have often been interpreted as being ‘context-dependent,’ i.e., being dependent on differences in the state of the ecosystems at the start of the experiments. It is not unlikely, however, that such contradicting results are in fact due to non-linear relations in climate change responses.

Pulse and press changes and ecological stability

Most climate change experiments address gradually developing, long-lasting climate-related changes (also called ‘press’ or ‘ramp’ changes), such as warming, but also investigate the impact of extreme events, such as of heat waves or torrential rain events (also considered ‘pulse’ changes). Such studies become more important as the frequency of these events is increasing. Both ‘press or ramp’ and ‘pulse’ changes can have strong and long-lasting effects on many ecosystem components, including soil. The ecological stability of an ecosystem is defined as the ability of a system to continue functioning under changing conditions or during disturbances. Thus, the stability can be measured by the degree of its resistance and resilience to change. Resistance is the degree to which a community or system withstands disturbances. The inverse of resistance is ecosystem sensitivity, which describes the degree to which an ecosystem or community responds to a disturbance. Resilience is the speed with which a system returns to its pre-disturbance level after a disturbance. Thus, resilience is a function of time. Based on the degree of resistance and resilience, ecosystems or communities can also shift to alternative (stable) states. Such shifts may easily go undetected as usually only a few groups of soil organisms and processes are measured in climate manipulation experiments. Finally, climate change experiments often fail to address how changes in the frequency of pulse disturbances or extreme events affects soil responses, which influence the dynamics of community living in soils.

Effects of climate change on soil organisms

In recent decades, our ability to characterize and describe the diversity and community composition of soil organisms has improved tremendously, largely due to the rapid advent of molecular techniques. Experimental evidence supports an important role of soil biodiversity for ecosystem processes such as plant growth and nutrient cycling. As such, understanding the effects of climate change on the diversity of soil micro- and macro-organisms represents a critical challenge (Zhou et al., 2020). Here, we summarize the general patterns for different groups of soil organisms in response to elevated atmospheric CO₂, warming and drought.

Bacteria, fungi and archaea

The effects of elevated atmospheric CO₂ on soil microbial communities are by no means consistent and occur rather indirectly in response to changed plant belowground carbon allocation and litter input. Overall, elevated atmospheric CO₂ seems to decrease bacterial diversity and evenness and to favor slow growing, resource-efficient oligotrophic microorganisms. For example, in a California grassland elevated atmospheric CO₂ decreased copiotroph Bacteroidetes, but increased bacteria with smaller rRNA copy numbers, a common trait of oligotrophs (Naylor et al., 2020). Similarly, a meta-analysis found that the response of fungal diversity to elevated atmospheric CO₂ was neutral, although fungal diversity increased when experiment duration was accounted for, indicating

that short-term experiments may underestimate the impact of elevated atmospheric CO₂ on soil microbial communities (Veresoglou et al., 2016).

Warming has been shown to stimulate microbial abundance, activity, and nutrient cycling rates, both in the short- and long-term, if water and nutrients are sufficiently available (Walker et al., 2018). Across several studies, warming alone did not change alpha-diversity (richness or Shannon-index) but clearly modified the community structure (Zhou et al., 2020). However, this is not always the case (Radujković et al., 2018), particularly for moderate increases in temperatures. Moreover, warming seems to have a stronger positive impact on fungal rather than on bacterial diversity, as well as to foster more specialized communities (Zhou et al., 2020). We would expect a particularly strong impact of warming in colder ecosystems as has been shown for other ecosystem components; however, across experiments, microbial diversity in tundra and temperate or boreal forests has shown responses in richness and Shannon index to warming similar to tropical and subtropical forests (Zhou et al., 2020). While scarce, information on the functional community diversity indicates no effects of warming or elevated atmospheric CO₂ (e.g., nitrifier communities, Séneca et al., 2020).

The response of microbial communities to changes in soil moisture, including drought periods and subsequent heavy rainfalls, is usually stronger than the response to warming. Common phylogenetically conserved features, such as osmolyte production, synthesis of capsules and exopolymeric substances to retain water, or dormancy and sporulation to avoid water deficit, can determine winning strategies between different microbial taxa. Yet, the effects of precipitation changes on soil microbial communities have shown contrasting effects across studies. Moderate increases in precipitation had stronger effects on microbial communities than moderate decreases, while the opposite was true for more extreme changes (Zhou et al., 2018). Thus, differences in the range of possible experimental manipulation (level of soil moisture changes compared to ambient conditions) and pre-existing environmental conditions (e.g., average precipitation experienced by different ecosystems) make comparisons across studies difficult.

The increase in frequency of drought events raises questions on the long-term impact of changing precipitation patterns. A recent study shows that long-term recurrent droughts can manifest changes in soil bacterial and fungal community and modify their response to a new drought event (Canarini et al., 2021). The authors show that recurrent droughts increase the dissimilarity of microbial communities, compared to control and single drought events, and enhance soil multifunctionality during drought (including key enzymes regulating soil organic matter decomposition). Thus, while drought events trigger specific changes in the community composition of both bacteria and fungi (Isobe et al., 2020), the dependency on drought severity and the long-term dynamics are still largely unknown. Finally, rewetting events that typically follow periods of drought, have also been shown to be very important for restructuring the soil community, and may have large effects on bacterial and fungal communities.

Soil fauna

Like microorganisms, soil animals are well-adapted to high CO₂ concentrations in soil, that regularly reach values of above 100,000 ppm in carbon rich soils. Elevated atmospheric CO₂ is thus unlikely to affect soil animals directly. However, its impact on plants could affect soil animals through modification of resource quality, quantity, soil moisture and other soil properties (e.g., changes in root exudation or modification of soil pH). In a meta-analysis of belowground responses to elevated atmospheric CO₂, A'Bear et al. (2014) reported limited changes in soil fauna community composition or abundance in response to elevated atmospheric CO₂. Observed changes were particularly limited to lower trophic levels, with reports of both reductions and increases in nematodes abundances. Collectively, elevated atmospheric CO₂ thus appears to have only limited and indirect effects on soil fauna, particularly with no changes at higher trophic levels which are less directly influenced by the plant community.

Moderate increases in temperature, i.e., a temperature increase that does not exceed the temperature optimum of a population, can reduce physiological constraints, which in turn favors the abundance and biomass of soil fauna, if other factors, such as water or nutrients, are not-limiting. This positive warming effect is the most likely driver of shifts in soil fauna species distribution toward the colder edge of species' range. Temperature increases can also negatively affect soil fauna if they exceed the optimal range of species. Warming can be indirectly detrimental to soil organisms by decreasing the soil water content, or by modifying the vegetation, which in turn alters the resource quality at the basis of the trophic network. The direction and magnitude of the warming effect may also depend on its timing as warming can reduce snow cover and thus expose soil animals to greater temperature fluctuations. Animal species requiring chilling period during their diapause may also be influenced by winter warming.

Drought is likely to reduce soil fauna density and biomass, albeit to varying degrees depending on soil fauna composition and ecosystem. Soil fauna encompass very diverse organisms, from single-celled protists to large multicellular organisms, such as earthworms or mammals. Consequently, their sensitivity to drought is not uniform, both among and within dominant groups. Microfauna, such as protists and nematodes are likely to be the most affected by drought. Many soil invertebrates can cope with seasonal or temporary drought through behavioral (avoiding drought by escaping in time or space) and physiological mechanisms (tolerance). Mainly, their mobility allows them to relocate to more favorable conditions, by burrowing deeper, sheltering in cavities, or surviving severe drought periods in developmental stages that are less prone to damage. Physiological mechanisms include the ability to obtain water from air vapor and to reduce their metabolism during dry periods. Larger soil fauna may also be more adapted to drought, by having lower surface-to-volume ratio and thus lower water loss rate. However, all these adaptations may not be sufficient to cope with more severe or prolonged drought. In addition to the group-specific nature of the soil fauna response to climate change, response may also depend on antecedent moisture conditions. Drought negatively affected predatory nematodes in mesic ecosystems, but not in xeric ecosystems (Franco et al., 2019). The nature of soil fauna response to drought may also depend on the timing of rainfall. In dryland ecosystems where soil moisture is limited and rainfall events are rare, soil biotic responses are controlled by a series of hierarchical thresholds in soil moisture with microorganisms responding to small rainfall events even at

low soil moisture, and soil invertebrates responding only to larger rainfall events inducing higher levels of soil moisture (Nielsen and Ball, 2015). Soil fauna may thus be more sensitive to changes in the timing and intensity of rainfall events than microorganisms. Yet, drought studies more often focus on changes in cumulative rainfall quantity using rainout shelters, leaving timing and frequency of rainfall events much less understood.

Viruses

Soil viruses are an important component of soil microbial communities, but the understanding of their role in the soil food-web is currently in its infancy, and their response to climate change is even less studied. Recent studies have shown that viruses may play an important role in mediating effects of climate change in certain ecosystems, by controlling the composition of the microbial community. In a permafrost thaw gradient, viral predators controlled key microorganisms for soil carbon cycling, including methanogens and methanotrophs (Emerson et al., 2018), and virus encoded enzymes were significant predictors of methane emissions. Thus, viruses may impact ecosystem functions in soils, but whether and how such phage-microbe interactions will be altered by climate change, remains to be elucidated.

Effect of climate change on interactions

Organisms do not live alone—they constantly interact with the individuals that live around them and with their abiotic environment. The sum of these interactions not only shapes community composition, but also greatly affects the ecosystem processes and services provided by soil (Fig. 1). The emerging behavior of micro-level interactions and soil food-web dynamics are thought to affect large-scale processes at the ecosystem level and can be prone to climate change effects. Climate change drivers thus not only affect each individual organism, but also affect the interaction of individuals and taxa at various levels. Soil fauna and microbial communities are very diverse, within a teaspoon of soil, for example, harboring tens of thousands of bacterial and fungal species. This diversity is mirrored by a large range of possible interactions (from chemical exchange to prey-predator relationship) spanning wide variation of the scale level. For example, microbial interactions mostly take place at a distance on the scale of tenth of μm , with an individual bacterial cell in soil interacting on average with about 120 other cells (Raynaud and Nunan, 2014). At the soil food-web level, inter-kingdom interactions can increase the scale to the centimeter or meter scale. The main challenge remains the ability to detect and measure these interactions within a community, especially at the lower end of possible spatial scales. A wide range of statistical (e.g., network analysis) and experimental approaches (e.g., microfluidics) are now being developed to increase our ability to characterize and manipulate microbial interaction at relevant scales. At a soil food-web level, inter-kingdom interactions can be approached by dividing soil food webs into bacterial, fungal, and a direct root energy channel (e.g., via root fungal symbionts and root-feeding nematodes). However, such different energy channels are not necessarily separated. Protists, for example, can have a wide range of feeding strategies, such as feeding on bacteria, fungi or even nematodes. While much work is underway to build classification systems of feeding relationships in soil, a detailed understanding of these traits is needed to improve our understanding of the soil food web. The 'channel concept' thus rather represents a framework that allows simplification of the testing of climate change effects on interactions at the soil community level.

Different climate change factors may of course cause different effects on the soil food web than on interactions among soil communities. Elevated atmospheric CO_2 induces rather indirect and modest alterations of soil biotic food webs by several mechanisms including changing soil water availability, plant productivity or rhizodeposition. Most plant species can form mutualistic associations with mycorrhizal fungi (arbuscular mycorrhizal fungi, AMF, or ectomycorrhizal fungi, EMF). Elevated CO_2 was shown to preferentially increase plant C allocation to AMF than to bacterial communities, followed by a slower release from AMF to the bacterial and fungal populations (Drigo et al., 2010). On the other hand, elevated atmospheric CO_2 also fosters fungal based food webs, such as of fungivorous relative to bacterivorous nematodes (Dam et al., 2017), or the density of ciliates, microarthropod detritivores or gamasid mites, which could exert a bottom-up effects on microarthropod taxa richness (Eisenhauer et al., 2012).

Warming can affect microbial interactions and their interaction with the soil fauna, but the direction of these effects is still largely unknown. Recent reports show that warming can either increase or decrease bacterial network properties (measured by network analysis) such as connectivity and stability (Zhou et al., 2021). When the analysis considers also other organisms (fungi and higher-level trophic groups) results vary across groups (Zhou et al., 2021). In two boreal-temperate ecotonal forests, warming was shown to alter energy flux to higher trophic organisms, with either increase or decrease depending on forest disturbance and presence of drought (Schwarz et al., 2017). This further reinforces the idea that climate change factors can have interactive effects also at the community interaction level.

Drought can strongly affect soil microbial interactions, with fungal-based food webs usually being more resistant to drought. The increase in resistance, however, has a trade-off, after drought ends with the lower resilience of fungal based energy channels relative to bacteria dominated energy channels. Indeed, drought promotes destabilizing network properties (analyzed by co-occurrence networks) in soil bacteria communities, but not in the fungal community (de Vries et al., 2018). Drought duration and the following rewetting events are also potentially important modulators of soil food web and microbial interactions. Reducing the frequency of precipitation without changing the overall rainfall amount, stabilized soil food webs (Andrés et al., 2017). Some studies highlight the possibility of stronger sensitivity of higher trophic levels during drought, and a stronger bottom-up control of soil processes (Siebert et al., 2019), with evidence that community and feeding activity of higher trophic groups (testate amoebae

and nematodes) were more strongly affected than soil microbial biomass and activity. Higher trophic groups were also reported to have unexpected interactive responses to changes in precipitation. For instance, increased growing-season precipitation reduced the overall nematode abundance (Franco et al., 2019). Although the litter-feeding activities of an isopod and millipede species were largely unresponsive to changes in precipitation, they consumed more litter in combination than separately, but this synergistic interaction disappeared under drought (Joly et al., 2021). Ultimately the type of ecosystem will determine the overall drought effects on soil food web. For example, primary inputs from plants can sustain the soil food web during drought, especially for species-rich plant communities (Cesarz et al., 2017), via strengthened mycorrhizal association or root-feeding nematodes.

Global change effects on soil processes

Soil faunal and microbial communities control and regulate soil fluxes of carbon and nutrients (e.g., soil C sequestration and soil organic matter stabilization, greenhouse gas emissions). Climate change can directly affect organisms, by causing changes to their growth, activity and turnover, and enzyme production rates, but also indirectly, by affecting water, carbon or nutrient availability. Soil biota are responsible for a wide range of processes occurring in the litter layer, bulk and rhizosphere soil. For example, soil meso- and macrofauna play a crucial role in fragmenting and decomposing plant organic matter. Similarly, soil fungal and bacterial communities are essential for plant and soil organic matter decomposition, as well as for depolymerizing and mineralizing nutrients bound in organic matter. Hence, their activity rates control soil carbon and nutrient turnover, as well as carbon outputs from heterotrophic soil respiration or nutrient cycling and availability for plants. Unsurprisingly, many of these processes will strongly respond to changing climatic conditions, which we discuss in more details below.

Elevated CO₂ effects

Increased atmospheric CO₂ can stimulate photosynthesis, which potentially increases the amount of carbon in plant biomass and litter. These observations have led to the 'CO₂-fertilization hypothesis,' which proposes that plant responses to increasing atmospheric CO₂ drive increases in ecosystem carbon storage, creating negative feedback to climate change by taking up atmospheric CO₂. Elevated atmospheric CO₂ has been shown to have negligible direct effects on soil processes (mainly at very high concentrations). However, in the short term, elevated CO₂ indirectly stimulates microbial activity and soil respiration rates, microbial biomass, and genetic signals for carbon cycling processes (Deng et al., 2015). Indeed, elevated atmospheric CO₂ can increase plant organic matter and root exudate inputs, which can promote fast-growing microorganisms in the rhizosphere and soil (Blagodatskaya et al., 2010). In the short term this can increase C inputs to the soil, the labile inputs can prime the break-down of labile and more complex soil carbon compounds (the 'priming effect') and level up heterotrophic soil respiration (Naylor et al., 2020). Over the long term, elevated atmospheric CO₂ may rather lead to increased 'new' C turnover in the soil or even induce C losses from ecosystems (van Groenigen et al., 2017). In contrast to C cycling processes, soil microbial N cycling seems to be less affected by elevated atmospheric CO₂, unless plants have a higher N (or P) demand, which could increase the competition of soil microbial communities and plants for N. A lack of either increased biological N fixation, or increased N mineralization rates has been shown to induce a progressive N limitation for plants, which on a decadal scale may reduce a potential 'CO₂ fertilization' effect on plants (Dieleman et al., 2010). Similarly, elevated atmospheric CO₂ may have little effects on soil microbial P cycling in the long-term (Ochoa-Hueso et al., 2019), although experimental data for effects on soil microbial P cycling are still scarce.

Warming effects

Warming can directly increase microbial decomposition by lowering the activation energy for enzyme-catalyzed reactions, that can induce higher specific activities of soil microbes (Walker et al., 2018). However, whereas warming might initially stimulate the metabolism of decomposers and thereby increase decomposition rates, evidence from long-term (> decade) experiments showed that the impact of warming rather decreases over time, so that in the long-term C losses induced by warming might be smaller than suggested by short-term warming studies. This pattern can be explained by a reduction in microbial biomass over time caused by a depletion of available resources (Walker et al., 2018), by adaptations or adjustments in microbial physiology of individual microbes or changes of microbial community composition and structure. Although warming may accelerate respiration and the growth of microorganisms, non-linear, interactive effects have been found when studying growth and respiration in response to elevated CO₂ and warming together (Simon et al., 2020).

The effect of warming on the contribution of soil fauna to soil processes remains unclear. Theory predicts that increased temperature should lead to increased animal activity to satisfy metabolic demand. Yet, in a 4-year climate change manipulation experiment in boreal forests, Thakur et al. (2018) reported negligible net effects of warming on detritivore feeding activity at ambient precipitation. The response of detritivore activity to warming may also be species-specific, with both positive and negative responses reported. Changes in soil fauna community as a result of warming however, could have important consequences on soil processes. For instance, potential detritivores expansion in subarctic ecosystems could stimulate litter decomposition (van Geffen et al., 2011). Earthworm expansion into the arctic was also found to accelerate organic matter turnover and N mineralization thereby facilitating plant productivity (Blume-Werry et al., 2020) and possibly leading to N losses.

Changes in precipitation

Moisture (or soil water availability) is essential for soil microbial activity. Changes in precipitation can thus have strong effects on soil processes. For example, drought reduces water in pore spaces, disconnects soil microhabitats, increases oxygen filled pore space and concentrates nutrients in the remaining soil water. All these changes have been shown to decrease soil microbial activity often measured as heterotrophic respiration rates. However, drier conditions can favor aerobic processes such as nitrification (although it may reduce anaerobic methane production). Overall soil carbon and nitrogen cycling accelerates with increased precipitation and slows down with decreased precipitation. Drought may also affect N and P cycling processes, although there is less information for increased precipitation. Drying and rewetting cycles mobilize available P to a greater extent than N (Gao et al., 2020). Although consequences for P losses or soil biology are not known, this could potentially induce an imbalance between N and P, especially in forest ecosystems. However, we currently lack a unifying theory explaining responses of microbial processes in soil to changes in precipitation. Currently-available data focuses mainly on trace gas fluxes as well as pools of carbon, nitrogen and phosphorous but the underlying processes remain largely unexplored. The main exception is soil respiration, of which, the response to varying soil moisture conditions is well studied. Furthermore, responses to changing precipitation regimes are often difficult to compare. Responses of soil respiration to drying and rewetting conditions largely depends on the intensity of drought and on the initial soil carbon content (Canarini et al., 2017). Especially the response of soil processes to rewetting can strongly change depending on the preceding drought conditions (Meisner et al., 2017). Many processes are difficult to measure during dry conditions, as measurements often require water addition. Beside changes in moisture and oxygen concentration, strong changes in substrate availability accompanied by changes in precipitation can affect soil processes. Therefore, responses of soil processes to drought might not be as straight forward to understand. For example, N₂O emissions during drought periods were dominated by anoxic denitrification processes, despite the drought leading to more oxygen filled pores in soil (Harris et al., 2021). The authors showed an enrichment in nitrogen-containing organic matter on soil microaggregates and suggested a role for chemo- or co-denitrification. The nitrification process, in turn, was quite resistant to drought, possibly due to enrichment in NH₄⁺ during drought and changes in community structure (Séneca et al. (2020).

Drought can negatively affect soil animals, yet faunal-driven litter decomposition appears to be relatively insensitive to drought, from arid to temperate or boreal ecosystems. In a Mediterranean forest, however, the increased rates of litter decomposition under a rainfall exclusion treatment, seemed to be driven by an increase in mesofauna abundance (Homet et al. (2021). This effect does not appear to be specific to dry environments, and litter consumption by an isopod and a millipede species was also not affected by halving rainfall quantity in a temperate forest (Joly et al., 2021). Collectively, these studies suggest that behavioral or physiological mechanisms to cope with drought allow soil animals to maintain their activity and contribution to soil processes.

Multiple climate change drivers

Different climate change drivers can have additive (similar or diametrical) or interactive effects on soil microbial C, N or P cycling. For example, warming could increase microbial activity and heterotrophic respiration, whereas simultaneous dry conditions may reduce microbial activity and reduce stimulating effects by higher temperatures. However, effects of different climate change drivers appear to be ecosystem-specific and depended on the history of the ecosystem. In a grassland ecosystem with experimentally simulated future climate (+3 °C warming in combination with +300 ppm CO₂ above ambient conditions), summer drought significantly increased microbial biomass-specific growth and respiration rates, while elevated atmospheric CO₂ alone did not have any impact on microbial C turnover (Simon et al., 2020). In a cold heathland ecosystem, climate manipulations (warming, drought, and elevated atmospheric CO₂) alone or in combination, did not change protein depolymerization rates, nitrogen mineralization, and amino acid and ammonium uptake showed no significant individual treatment effects (Wild et al., 2018). In a grassland ecosystem, warming and elevated atmospheric CO₂ had only minor effects on nitrifier communities and soil biogeochemical variables (Séneca et al., 2020).

Summary and conclusion

Soils and their biota are an integral part of all terrestrial ecosystems and are key components in the interaction of terrestrial ecosystems with the atmosphere. Climate change can directly or indirectly affect individual organisms and species, and their interactions, thereby affecting soil community composition and processes. Above all, soil biota plays the central role in organic matter decomposition in terrestrial ecosystems, regulating soil organic matter formation (via microbial growth or turnover and necromass production) as well as greenhouse gas release to the atmosphere, which in turn can lead to positive or negative feedbacks to climate change (Fig. 1). Moreover, microbial activity is closely dependent on soil faunal activity, via predation and resource provisioning. The large diversity of soil fauna with contrasting structures, life cycles, reproduction strategies, food sources, and adaptive strategies to environmental change makes climate change effects on soil organisms difficult to generalize. Given the highly interconnected nature of the soil food web and the small spatial scale at which many interactions occur, the effect of climate change on soil organisms cannot be simply understood based on individual responses of these contrasted soil organisms, but shows emergent behavior, making it difficult to predict alterations in soil functions and services in response to climate change.

We have shown above that global climate change affects all soil organisms, from bacteria to soil vertebrates and their interactions, in various ways, directly and indirectly. The concurrent drivers of climate change can act in additive as well as interactive ways and can exhibit nonlinear behaviors. Traditionally, large scale climate change experiments (i.e., field experiments) were set-up from a plant-centric view rather than an ecosystem perspective. For example, most experiments are only conducted during the growing seasons, ignoring the activity of soil organisms during winter or the dry season, when many plants are not active. Thus, we clearly need more integrated climate change experiments that recognize soils and soil biota as equally important components of ecosystems as vegetation. We also need more experiments which are explicitly designed to understand effects on soil biota and the processes they mediate, to disentangle underlying mechanisms and their feedback to vegetation in a future climate. For example, current studies often focus on the very top centimeters of soil, and we lack understanding on how deep soil layers (and the communities within) will be affected by climate change. We also need to initiate climate change experiments which specifically target the manipulation of soil organism and communities, to start addressing causal relationships between climate change effects on soil organisms and the processes they control.

Given all the challenges facing humanity, research into soil organisms, their interactions and processes in a changing climate is crucial if we are to understand the impacts of global climate change on terrestrial ecosystems and how soils can help mitigate climate change.

EDITORS BIOGRAPHY

Michael J Goss, PhD, MSc, BSc, is a professor emeritus in the School of Environmental Sciences at the University of Guelph. Before taking on the joint editor-in-chief responsibilities with Margaret Oliver, he held a similar position for *Soil Use and Management*, a journal of the British Society of Soil Science of which he is an honorary fellow. He was an inaugural member of the European Society for Agronomy. Michael started his career at the Letcombe Laboratory before moving to Rothamsted Experimental Station and the Macaulay Land Use Research Institute (now the James Hutton Research Institute). In 1990 he was appointed to the Research Chair in Land Stewardship at the University of Guelph and in 2005 became the director of its Regional Campus near Ottawa.

Michael's research has covered soil plant relations, soil management, and agriculture's footprint on the environment. His focus has been on the physical properties of soil and their impacts on root growth, which he showed to be influenced by the role of the root cap. He broadened his approach to include the effects of tillage and land drainage on root exploration. This work stimulated his interest in the transport of materials, such as plant nutrients, pathogenic microbes, antibiotics, and biologically active compounds through the soil and their contamination of water resources. Michael's knowledge in this field resulted in his involvement in the public inquiry into the death of seven people, including children, from a microbially contaminated drinking water supply. He contributed, both to the investigation into how the contamination occurred and if any fault could be attributed to local agricultural practices, and to how to prevent future events.

Michael also developed an interest in the interrelationships between soil microbes and root systems, particularly the tripartite symbiosis between roots of legumes, mycorrhizal fungi, and rhizobia. He has been an energetic member of collaborative research programs in France and Germany, and in Portugal, where he continues his interest in the role of mycorrhiza in sustainable land management.

Michael has authored more than 180 publications including two books, one in its 2nd edition, and edited two others.

Margaret Ann Oliver (BSc, PhD)

Margaret's interest in soil began in her penultimate year at school when learning about different types of soil and their formation. She chose the University of Bristol, United Kingdom for her first degree because the geography course offered soil science and she was also able to do a degree in geology alongside. Her love for both subjects remains undiminished. She did her PhD in soil spatial analysis at the University of Birmingham. Her early research focused on the multivariate and geostatistical analysis of soil data, which she continued to use in various research projects. Her research interests expanded to include the application of a wide range of numerical and geostatistical methods to soil and other data including pollen counts, forestry, radon emission, remotely sensed imagery, precision agriculture, and the incidence of childhood cancer. Her specific interests have been in sample design for spatial analysis and eventual mapping, risk analysis associated with prescribed thresholds in relation to soil pollutants or deficiencies of crop nutrients, and the relations between different scales of spatial variation. Her most

recent research was in the field of precision agriculture. At both the Universities of Birmingham and Reading, she taught topics in soil science, statistical methods, and spatial analysis. At Reading she had a research group working on various projects such as imagery, sampling and mapping, precision agriculture, and human health.

She has published more than 100 academic papers and has made several contributions to books. She is the co-author of three books: *Statistical Methods in Soil and Land Resource Survey*, Oxford University Press (Webster, R and Oliver, M. A. 1990); *Geostatistics for Environmental Scientists*, Second Edition, John Wiley & Sons (Webster, R and Oliver, M. A. 2007), and *How to do the Basic Steps in Geostatistics: The Variogram and Kriging*, Springer, Dordrecht (Oliver, M.A. & Webster, R.2015). She has edited two books: *Geostatistical Applications for Precision Agriculture* (Springer, Dordrecht, 2010) and *Precision Agriculture for Sustainability and Environmental Protection* (Earthscan from Routledge, 2013).

Margaret retired officially from Reading in 2004, but as yet has not managed to escape from academia. She has retained a link and a base at the University as a visiting professor since January 2005. After retirement, she developed and taught geostatistics courses to outside groups for several years. She then started on the long path of editorial work, as an associate editor of the *European Journal of Soil Science* and eventually the editor-in-chief, assistant editor of *Mathematical Geosciences*, co-editor of *Precision Agriculture* with John Stafford, and finally the editor-in-chief of the *Encyclopedia of Soils in the Environment* with Michael Goss.

Margaret was made an honorary member of the British Society of Soil Science in 2021 to reflect her commitment to soil science through fellow research, teaching, and editorial work. She was honored by the Pedometrics Commission of the International Union of Soil Science by having an award named after her in 2015. It is the Margaret Oliver award for young pedometricians.

FOREWORD

Soil is the porous “skin” on the surface of the Earth that has formed over thousands of years of weathering, comprising minerals, organisms (both dead and alive), water, and air. Soil is more than just the sum of its parts. It serves several crucial ecological functions, from food and fiber production to water storage and purification to waste decomposition.

Increasingly we understand that everything is connected, and that soil is a “Critical Zone” that intersects with the hydrosphere (water), lithosphere (minerals), atmosphere (air), and biosphere (all living organisms). To quote Daniel Hillel, the 2012 World Food Prize laureate and editor of the First Edition of *The Encyclopedia of Soils in the Environment*, “[Soil] is the crucible of terrestrial life, within which biological productivity is generated and sustained... Our civilization depends on the soil...” He also promoted the importance of understanding soil to manage it effectively. This revised and reorganized second edition of the Encyclopedia aims to reflect the changing status of soil in the world. Within these five volumes, over 724 experts from many countries have provided updated, easy-to-understand chapters on soil, its properties, and its role in the environment to affect climate change, plant productivity, human health, and biodiversity.

Many technological advances have been made since the first edition of this encyclopedia that has allowed us to investigate soil physical, chemical, and especially biological properties more precisely, enabling us to identify and understand their roles in ecosystem services. The study of soils, especially in the environmental context, is critical to meeting the challenges of feeding, clothing, and cleaning up the world. The information presented in these volumes will be useful to many, including soil and environmental scientists, policymakers, land managers, educators, students, and anyone interested in learning more about soil.

Soil is under considerable threat from many sources—building and infrastructure, climate change, population pressure, and pollution, yet it is vital to agronomic productivity and continues to provide critical ecosystem services. Society needs to be engaged in how soil is managed and conserved. Most natural scientists are very dedicated and generous, including all of the authors in this Encyclopedia who have freely given their time to make these volumes so comprehensive. The study of soil, while often challenging, is fascinating—soil is a beautiful earthy material that can delight our senses with its variegated colors, gritty to smooth textures, and especially its characteristic aroma when freshly turned. Perhaps that is why gardeners and even some farmers tend to overwork their soil to its detriment—it *just feels good to get your hands in the dirt!*

Soil science is one of the most exciting, interesting, and rewarding disciplines, largely because it is multi-dimensional and interdisciplinary, basic and applied. It affects all of our lives. Thus, I encourage you to peruse these volumes and discover all kinds of interesting aspects of soil in the environment.

April Ulery

Former President, Soil Science Society of America
Professor, Soil & Environmental Sciences
New Mexico State University
Las Cruces, NM

PREFACE

This second edition of the *Encyclopedia of Soils in the Environment* follows in the footsteps of a highly rated first edition overseen by Professor Daniel Hillel as editor in chief, ably assisted by six editors. That edition provided a very valuable resource on the “state-of-the-art” in soil science in the context of the environment in the closing years of the twentieth century and the first three years of the current century. It set a standard that the editorial team for the second edition has aimed to match. The soil and environmental sciences have made huge strides in the almost 20 years since the first edition was published, and the new team has had to embrace these developments while retaining the basic components of these sciences. The project has taken 4 years to complete. It began with the appointment of the two editors-in-chief, professors Michael J. Goss and Margaret A. Oliver, followed by that of the nine subject editors and a pedology adviser.

The project was in its infancy (a few months only) when COVID-19 struck. The editors-in-chief discussed the format and structure of the second edition around the time that the first “lockdowns” around the world were being introduced. The first edition was alphabetically organized, whereas we decided to have a section-oriented approach in this edition, which we hope gives a more structured feel for the various topics embraced. The principal sections are soil biology, soil chemistry, the soil environment and its management, pedology (the origins and development of soil), pedometrics (the application of mathematics and statistics to soil), and soil physics. We were able to give our full attention to this development and to the selection of the scientists to join us on the road ahead. Furthermore, we were fortunate to choose a team that has maintained its enthusiasm despite the many tribulations we have faced along this path. The team comprises Jane Blagodatskaya and Adrian Unc (biology and microbiology), Siobhan Staunton and Baoshan Xing (chemistry), Karin Müller and Christina Siebe (environment and management), Rupert Bäumler (pedology), Uta Stockmann and Margaret Oliver (pedometrics), and Paul Hallett and Dani Or (physics). The editorial board has been mindful in their choice of subjects of the need for basic soil science and for state-of-the-art developments, with the aim that the audience for these volumes can be as large as possible.

During the gestation period of the Encyclopedia, methods of working for those in academia were turned on their heads. The change from “face-to-face” teaching to formulating and establishing online courses, initially for lockdown periods but then for much of the next 2 years, had huge consequences for academic staff worldwide. This meant that they had less time to devote to outside activities, such as writing chapters for an encyclopedia. As a result, some authors were unable to complete their chapters in time, leaving a few unfortunate gaps. The whole team has done as much as they can to limit any adverse effects, but we ask readers to appreciate the struggle that authors have had with illness (personal, within their families and work colleagues) and a great increase in their workload. Despite this, we are presenting a comprehensive document that should stand the test of the next 20 years of soils in the environment.

This century has seen an almost unprecedented interest in the soil and environmental sciences. It has been triggered not only by issues that the Earth is facing from global climate change, increasing population pressure, soil and land degradation, and food insecurity but also by the many new and sophisticated methods available, such as the DNA determination of microbial populations and their functional capabilities, proximal sensing, machine learning methods, and an ever-increasing array of technological tools. These developments have greatly increased our knowledge and appreciation of the complexity of soils, which has changed our understanding of some well-established aspects of the science. The soil and its environment are at the critical interface of the atmosphere, biosphere, hydrosphere, and lithosphere. They deserve to be taken seriously by the international community in the same way that air and water have been. Governments are now paying attention

to the soil and environment, and a legal and governance framework is emerging to look after these parts of our life support resources.

We have aimed, through our editing of chapters, to make the language of the chapters accessible to all, regardless of educational background. This does not mean that we have diminished the scientific content, but that readers should be able to gain the foothold they desire in these subjects to progress to greater knowledge and understanding of them. We have retained the overview of soil written by Daniel Hillel for the First Edition, first to honor his great contribution to soil science and second to demonstrate the significance of soil. It follows this Preface.

*Michael J. Goss
Margaret A. Oliver*

SOIL

The term “soil” refers to the weathered and fragmented outer layer of our planet’s land surfaces. Formed initially through the physical disintegration and chemical alteration of rocks and minerals by physical and biogeochemical processes, soil is influenced by the activity and accumulated residues of a myriad of diverse forms of life. As it occurs in different geologic and climatic domains, soil is an exceedingly varied body with a wide range of attributes.

Considering the height of the atmosphere, the thickness of the earth’s rock mantle, and the depth of the ocean, one observes that soil is an amazingly thin body—typically not much more than one meter thick and often less than that. Yet it is the fount of terrestrial life, within which biological productivity is generated and sustained. It acts like a composite living entity, a home to a community of innumerable microscopic and macroscopic plants and animals. A mere fistful of soil typically contains billions of microorganisms, which perform vital interactive biochemical functions. Another intrinsic attribute of the soil is its sponge-like porosity and its enormous internal surface area. That same fistful of soil may actually consist of several hectares of active surface, upon which physicochemical processes take place continuously.

Realizing humanity’s utter dependence on the soil, ancient peoples, who lived in greater closeness to nature than many of us today, actually revered the soil. It was not only their source of livelihood but also the material from which they built their homes and that they learned to shape, heat, and fuse into household vessels and writing tablets (ceramics, made of clayey soil, being the first synthetic material in the history of technology). In the Bible, the name assigned to the first human was Adam, derived from “adama,” meaning soil. The name given to the first earthling’s mate was Hava (Eve, in transliteration), meaning “living” or “life-giving.” Together, therefore, Adam and Eve signified quite literally “Soil and Life.”

The same powerful metaphor is echoed in the Latin name for human species—Homo, derived from humus, the material of the soil. Hence, the adjective “human” also implies “of the soil.” Other ancient cultures evoked equally powerful associations. To the Greeks, the earth was a manifestation of Gaea, the maternal goddess who, impregnated by Uranus (god of the sky), gave birth to all the gods of the Greek pantheon.

Our civilization depends on the soil more crucially than ever because our numbers have grown while available soil resources have diminished and deteriorated. Paradoxically, however, even as our dependence on the soil has increased, most of us have become physically and emotionally detached from it. Many of the people in the so-called developed countries spend their lives in the artificial environment of a city, insulated from direct exposure to nature, and some children may now assume as a matter of course that food originates in supermarkets.

Detachment has bred ignorance, and out of ignorance has come the delusion that our civilization has risen above nature and has set itself free of its constraints. Agriculture and food security, erosion and salination, degradation of natural ecosystems, depletion and pollution of surface waters and aquifers, and decimation of biodiversity—all these processes, which involve the soil directly or indirectly, have become abstractions to many people. The very language we use betrays disdain for that common material underfoot, often referred to as “dirt.” Some fastidious parents prohibit their children from playing in the mud and hurry to wash their “soiled” hands when the children nonetheless obey an innate instinct to do so. Thus, soil is devalued and treated as unclean though it is the terrestrial realm’s principal medium of purification, wherein wastes are decomposed and nature’s productivity is continually rejuvenated.

Scientists who observe soil closely see it in effect as a seething foundry in which matter and energy are in constant flux. Radiant energy from the sun streams onto the field and cascades through the soil and the plants growing in it. Heat is exchanged, water percolates through the soil’s intricate passages, and plant roots extract

water and transmit it to their leaves, which transpire it back to the atmosphere. Leaves absorb carbon dioxide from the air and synthesize it with soil-derived water to form the primary compounds of life. Oxygen emitted by the leaves makes the air breathable for animals, which consume and in turn fertilize plants.

Soil is thus a self-regulating bio-physio-chemical factory, processing its own materials, water, and solar energy. It also determines the fate of rainfall and snowfall reaching the ground surface—whether the water thus received will flow over the land as runoff, or seep downward to the subterranean reservoir called groundwater, which in turn maintains the steady flow of springs and streams. With its finite capacity to absorb and store moisture, and to release it gradually, the soil regulates all these phenomena. Without the soil as a buffer, rain falling over the continents would run off entirely, producing violent floods rather than sustained river flow.

Soil naturally acts as a living filter, in which pathogens and toxins that might otherwise accumulate to foul the terrestrial environment are rendered harmless. Since time immemorial, humans and other animals have been dying of all manner of diseases and have then been buried in the soil, yet no major human disease is transmitted by it. The term antibiotic was coined by soil microbiologists who, as a consequence of their studies of soil bacteria, specifically actinomycetes, discovered streptomycin (an important cure for tuberculosis and other infections). Ion exchange, a useful process of water purification, also was discovered by soil scientists studying the passage of solutes through beds of clay.

However unique in form and function, soil is not an isolated body. It is, rather, a central link in the larger chain of interconnected domains and processes comprising the terrestrial environment. The soil interacts both with the overlying atmosphere and the underlying strata, as well as with surface and underground bodies of water. Especially important is the interrelation between the soil and climate. In addition to its function of regulating the cycle of water, it also regulates energy exchange and surface temperature.

When land is cleared of vegetation and turned into a cultivated field, the native biomass above the ground is often burned and the organic matter within the soil tends to decompose. These processes release carbon dioxide into the atmosphere, thus contributing to the Earth's greenhouse effect and to global warming. On the other hand, the opposite act of afforestation and soil enrichment with organic matter, such as can be achieved through conservation management, may serve to absorb carbon dioxide from the atmosphere. To an extent, the soil's capacity to store carbon thus helps to mitigate the greenhouse effect.

Thousands of years are required for nature to create life-giving soil out of sterile bedrock. In only a few decades, however, unknowing or uncaring humans can destroy that wondrous work of nature. In various circumstances, mismanaged soils may be subject to erosion (the sediments of which tend to clog streambeds, estuaries, lakes, and coastal waters), to leaching of nutrients with attendant loss of fertility and eutrophication of water bodies, to waterlogging and impaired aeration, or to an excessive accumulation of salts that may cause a once-productive soil to become entirely sterile. Such processes of soil degradation, sometimes called "desertification," already affect large areas of land.

We cannot manage effectively and sustainably that which we do not know and thoroughly understand. That is why the tasks of developing and disseminating sound knowledge of the soil and its complex processes have assumed growing urgency and importance. The global environmental crisis has created a compelling need for a concentrated, concise, and definitive source of information—accessible to students, scientists, practitioners, and the general public—about the soil in all its manifestations in nature and in relation to the life of humans.

Daniel Hillel

CONTENTS OF ALL VOLUMES

VOLUME 1: SOIL BIOLOGY

Overview

Edaphology	1
<i>RM Goss and AL Ulery</i>	

Biodiversity	10
<i>Monica A Farfan and Diana H Wall</i>	

Soil organisms

Bacteriophage (Viruses)	16
<i>Li Bi, Ji-Zheng He, Dan-Ting Yu, Li-Li Han, and Hang-Wei Hu</i>	

Archaea	25
<i>Mikhail V Semenov</i>	

Bacteria	31
<i>Mikhail V Semenov</i>	

Soil protists	39
<i>Stefan Geisen, Nathalie Amacker, and Alexandre Jousset</i>	

Fungi including mycorrhizal fungi	49
<i>F Buscot</i>	

Soil algae	61
<i>Karen Baumann and Patrick Jung</i>	

Soil arthropods: Underfoot and all around	70
<i>Ernest C Bernard</i>	

Nematodes	105
<i>Deborah A Neher and Thomas O Powers</i>	

Earthworms: Essential ecosystem engineers providing vital ecosystem services	112
<i>Maria JI Briones</i>	

Complex structures

Soil biofilms: Evolving concepts and ecological functions	120
<i>Yichao Wu, Marc Redmile-Gordon, Peng Cai, Chunhui Gao, and Qiaoyun Huang</i>	

Biocrusts	127
<i>Matthew A Bowker, Jasmine Anenberg, Hilina Yohannes Kebede, Anita Antoninka, and Lydia Bailey</i>	

Functioning

Studying soil microbial communities: Culture-dependent approaches	139
<i>Eduardo K Mitter, Dasiel Obregon, Micaela Tosi, Heather Slinn, and Kari Dunfield</i>	

Studying soil microbial communities: Culture-independent approaches	146
<i>Tolulope Mafa-Attoye, Heather Slinn, Micaela Tosi, Evan Mayer, Dasiel Obregon, and Kari Dunfield</i>	

Studying microbial function in soil: Culture-independent techniques <i>Micaela Tosi, Dasiel Obregon, Heather Slinn, and Kari Dunfield</i>	155
Kinetics of microbial processes: General principles <i>NS Panikov</i>	168
Kinetics of microbial processes: Applications to soil biology <i>NS Panikov</i>	186
Biogeochemical cycles	
Carbon cycle in soils: Dynamics and management <i>Charles W Rice, Carlos B Pires, and Marcos VM Sarto</i>	219
Carbon storage in soils <i>Isabelle Basile-Doelsch, Tiphaine Chevallier, Marie-France Dignac, and Amandine Erktan</i>	228
Soil organic nitrogen <i>EJ Daly and KA Congreves</i>	243
Nitrification: Process, organisms and management <i>Jeanette M Norton and Yang Ouyang</i>	253
Microbial denitrification <i>Michael J Goss, Sergey Blagodatsky, and Adrian Unc</i>	261
Symbiotic nitrogen fixation <i>Florence Mus and Hsin-Hua Wu</i>	270
Nitrogen: Non-Symbiotic Nitrogen fixation in soils <i>Vadakattu VSR Gupta and Sarah S Roley</i>	283
Phosphorus in soils—Biological interactions <i>Nataliya Bilyera and Iryna Loginova</i>	293
Biological transformations of sulfur in soil <i>Chaoqun Wang and Maxim Dorodnikov</i>	303
Plant uptake of mineral nutrients <i>Angela Hodge</i>	310
Higher plants and their interactions with soil organisms	
Soil Biology: Root form and function <i>Magda Garbowski, Grégoire Freschet, Louise Jackson, Cynthia Brown, and Louise Comas</i>	321
Root mucilage: Chemistry and functions in soil <i>Yutong Jiang, Lijun Hou, Fang Ding, and Joann K Whalen</i>	332
Root exudates and microorganisms <i>Aidan De Sena, Krisztina Mosdossy, Joann K Whalen, and Chandra A Madramootoo</i>	343
Root interactions with the microbiome from the rhizoplane to the bulk soil: An overview <i>Joann K Whalen and Shamim Gul</i>	357
Microorganisms & biological processes	
Soil respiration <i>Jeremiah D Vallotton, Sergey Blagodatsky, and Adrian Unc</i>	369
Anaerobic soil processes <i>PW Inglett, D Said-Pullicino, and K Ramesh Reddy</i>	379
Mineral-organic-microbial interactions <i>Balwant Singh, Sabina Yeasmin, and Donald L Sparks</i>	387

Microbial ecology & management

Habitat for soil organisms and their functions <i>Alexandra Kravchenko and Andrey Guber</i>	407
Plant growth promoters <i>Elisa Gamalero, Gustavo Santoyo, and Bernard R Glick</i>	418
Inoculation with microorganisms <i>Maureen O'Callaghan and David Wright</i>	428
Biocontrol of soil-borne plant diseases <i>Mehrdad Mohammadiani and Matthew Bakker</i>	439
Management of soil biology for crop protection from biotic and abiotic stresses <i>Michael J Goss, Isabel Brito, and Mário Carvalho</i>	447
Trees, hedges, agroforestry and microbial diversity <i>Josiah B Judson, Joseph Holden, Pippa Chapman, and Marcelo Valadares Galdos</i>	469
Urban soil microbiome: Activity, diversity and functioning <i>Maria Korneykova, Ekaterina Kozlova, Kristina Ivashchenko, Maria Vasilieva, and Viacheslav Vasenev</i>	480
Microbiology of extreme soil environments <i>Patrice Dion</i>	494
Microbial mobility and transport in soils <i>Mohammad Reza Mosaddeghi, Adrian Unc, Ali Akbar Mahboubi, and Azadeh Safadoust</i>	512

Biology of soil amendments & contaminant degradation

Biology of compost <i>Heribert Insam, Thomas Klammersteiner, and María Gómez-Brandón</i>	522
Landfarming and its microbiology <i>Naga Raju Maddela, Balasubramanian Ramakrishnan, Kadiyala Venkateswarlu, and Mallavarapu Megharaj</i>	533
Biodegradation of organic contaminants <i>PB Hatzinger and JW Kelsey</i>	547
Biological aspects of manure management <i>Natasha Rayne and Bee Khim Chim</i>	558
Septic systems and municipal waste disposal on land <i>Charles P Gerba, Michael J Goss, and Adrian Unc</i>	567

Climate change

Climate change impacts on soil biology <i>Alberto Canarini, Lucia Fuchslueger, François-Xavier Joly, and Andreas Richter</i>	578
---	-----

VOLUME 2: CHEMISTRY**Basic Soil Chemistry**

Acidity and acidification <i>Siobhan Staunton</i>	1
pH <i>Siobhan Staunton</i>	8
Buffering capacity <i>Siobhan Staunton and Ravi Naidu</i>	15
Soil specific surface area <i>Emmanuel Arthur, Markus Tuller, and Kurt D Pennell</i>	22

Soil Analytical Chemistry

Cation exchange capacity and reactions <i>Donald S Ross and Ulf Skyllberg</i>	32
Testing for nutrients in the soil and the environment <i>Antonio P Mallarino</i>	43
Metal extraction and analysis <i>Guo Wang and Honghong Li</i>	50
Soil organic matter: Composition <i>Markus Kleber</i>	58
Physical fractionation techniques <i>Sam J Leuthold, Michelle L Haddix, Jocelyn Lavallee, and M Francesca Cotrufo</i>	68

Abstract

Soil pH is an important property and may determine land-use and quality. Few crops are well adapted to acid soils and so amendments and management are sought to alkalize or limit further acidification. This chapter reviews the various processes that influence soil acidity. The effects of industrial activity and farming are considered. Two important industrial processes are acid drainage following pyrite oxidation and acid precipitation, best known as 'acid rain'. The cycling of C (carbon), N (nitrogen) and S (sulfur) induce changes in acidity and each of these is examined. The measurement of soil pH is briefly discussed. The adverse effects of soil acidity and countermeasures are also considered.

Key points

- Soils may be acidified by industrial and agricultural activity
- Liming and appropriate land use may mitigate acidification

Introduction

A large number of soils worldwide, particularly highly weathered tropical soils, are moderately to extremely acid (Ulrich and Sumner, 1991; Rengel, 2003; Kipling, 2022). Acid soils often have marked vertical pH gradients, depending on the origin of acidity; acid topsoils under forests, but acid subsoils in many Australian soils (Condon et al., 2021). A restricted number of crops are well adapted to very acid soils, but in general, these soils are considered to be of poor quality for agriculture (Hartemink and Barrow, 2023). At acid pH, cations such as calcium (Ca^{2+}) and magnesium (Mg^{2+}) on the exchange complex are replaced by protons and aluminum (Al), leading to aluminum toxicity. Soil acidification is a natural process that can either be accelerated by certain plants and human activities or slowed down by careful management practices (Fageria and Nascente, 2014). Industrial and mining activities lead to soil acidification due to acid produced from pyrite oxidation and from acid precipitation caused by the emission of sulfur (S) and nitrogen (N) gases. Acid precipitation has been significantly reduced in recent decades (Gilliam et al., 2019). In managed ecosystems, soil acidification is mainly caused by the release of protons (H^+) during the transformation and cycling of carbon (C), N, and S, and fertilizer reactions. Soil acidification caused by these processes can have adverse effects where soils are unable to buffer against further decrease in pH. For example, in parts of North America and Europe, soil acidification caused by acid precipitation has resulted in forest decline, and in some parts of Australia, continuous legume cultivation and inappropriate use

of N fertilizer have generated sufficient soil acidity that cereal crop cultivation has had to be abandoned because of aluminum (Al) and manganese (Mn) toxicity.

Historically, liming is the most common management practice used to neutralize soil acidity. Most plants grow well in the pH range 5.5–6.5, and the usual objective of liming programs is to maintain pH in this range. Liming enhances the physical, chemical, and biological properties of soil through its direct effect in ameliorating soil acidity and through its indirect effects in mobilizing plant nutrients, immobilizing toxic 'heavy metals', and improving soil physical conditions. In variable-charge soils, liming can be used as a management tool to manipulate the surface charge, thereby controlling the reactions of nutrient ions and metals. Liming provides optimum conditions for several biological processes, including N₂ fixation and mineralization of N, phosphorus (P), and S. Biochar is now often used to alkalize soils.

Processes generating acidity in soils

Processes generating acidity in soils can be broadly grouped into two categories: (1) those occurring in natural ecosystems through industrial activities, and (2) those occurring in managed ecosystems because of farming activities. The various reactions involved in these processes are given in Table 1.

The two important acid-generating processes resulting from industrial activities in natural ecosystems are acid drainage following pyrite oxidation and deposition of acidity in precipitation. While the first process occurs at a local level, the second process can lead to acidification far from the source of acid production and hence an international effort is needed to combat it.

Acid drainage

Acid drainage has both anthropogenic and natural origins, including mining of coal and sulfide-containing metal ores, land disturbances (e.g., rice (*Oryza sativa* L.) cultivation), and industrial activities (mineral processing, manufacturing or recycling of batteries, electronic equipment, wood pulp, tanneries and textile manufacturing, and food processing).

Pyrite is commonly associated with coal and metal ores, as well as mine deltas, wetlands, and rice fields. Exposure of pyrite to the atmosphere leads to its oxidation and the production of extremely acidic drainage water. Pyrite oxidation includes biological and electrochemical (abiotic) reactions (Table 1). Abiotic oxidation of pyrite is pH-sensitive and it is extremely slow in very acidic conditions. The bacteria *Thiobacillus ferrooxidans* and *Thiobacillus thiooxidans* are mainly responsible for the oxidation of pyrite, especially in acid soils.

Table 1 Proton generation and consumption processes in the soil-plant system, including those associated with acid precipitation, pyrite oxidation, and the C, N, and S biogeochemical cycles.

Process Reaction	Equations	H ⁺ (mol _e mol ⁻¹)	Equation number
<i>Acid precipitation</i>			
Oxidation of sulfur dioxide	2SO ₂ + O ₂ → 2SO ₃	0	1.1
Hydrolysis of sulfur trioxide	SO ₃ + H ₂ O → H ₂ SO ₄ → SO ₄ ²⁻ + 2H ⁺	+2	1.2
Photochemical oxidation of nitric oxide	O ₃ + NO → N ₂ O + O ₂	0	1.3
Hydrolysis of nitrogen dioxide	NO ₂ + H ₂ O → HNO ₃ + HNO ₂ → NO ₃ + H ⁺	+1	1.4
<i>Pyrite oxidation</i>			
Pyrite oxidation by oxygen	2FeS ₂ + O ₂ + H ₂ O → 2Fe ²⁺ + 4SO ₄ ²⁻ + 4H ⁺	+2	2.1
Ferrous iron oxidation	4Fe ²⁺ + O ₂ + 4H ⁺ → 4Fe ³⁺ + 2H ₂ O	-1	2.2
Ferric iron precipitation	Fe ³⁺ + 3H ₂ O → Fe(OH) ₃ + 3H ⁺	+3	2.3
Pyrite oxidation by ferric iron	FeS ₂ + 14Fe ³⁺ + H ₂ O → 15Fe ²⁺ + 2SO ₄ ²⁻ + 16H ⁺		2.4
<i>Carbon cycle</i>			
Dissolution of carbon dioxide	CO ₂ + H ₂ O → H ₂ CO ₃ → H ⁺ + HCO ₃ ⁻	+1	3.1
Synthesis of organic acid	Organic C → RCOOH → RCOO ⁻ + H ⁺	+1	3.2
<i>Nitrogen cycle</i>			
N fixation	2N ₂ + 2H ₂ O + 4R'OH → 4R-NH ₂ + 3O ₂	0	3.3
Mineralization of organic N	R-NH ₂ + H ⁺ + H ₂ O → R-OH + NH ₄ ⁺	-1	3.4
Urea hydrolysis	(NH ₂) ₂ CO + 3H ₂ O → 2NH ₄ ⁺ + 2OH ⁻ + CO ₂	-1	3.5
Ammonium assimilation	NH ₄ ⁺ + R'OH → R-NH ₂ + H ₂ O + H ⁺	+1	3.6
Ammonia volatilization	NH ₄ ⁺ + OH ⁻ → NH ₃ + H ₂ O	+1	3.7
Nitrification	NH ₄ ⁺ + 2O ₂ → NO ₃ ⁻ + H ₂ O + 2H ⁺	+2	3.8
Nitrate assimilation	NO ₃ ⁻ + 8H ⁺ + 8e ⁻ → NH ₃ + 2H ₂ O + OH ⁻	-1	3.9
Denitrification	4NO ₃ ⁻ + 4H ⁺ → N ₂ + 5O ₂ + 2H ₂ O	-1	3.10
<i>Sulfur cycle</i>			
Mineralization of organic S	2Organic S + 3O ₂ + 2H ₂ O → 2SO ₄ ²⁻ + 4H ⁺	+2	3.11
Assimilation of sulfate	2SO ₄ ²⁻ + 8H ⁺ + 8e ⁻ → SH ₂ + 2H ₂ O + 2OH ⁻	-2	3.12
Oxidation of S ⁰	2S ⁰ + 2H ₂ O + 3O ₂ → 2SO ₄ ²⁻ + 4H ⁺	+2	3.13

Acid precipitation

Carbon dioxide (CO_2) combines with water to form a dilute solution of carbonic acid (H_2CO_3) with an equilibrium pH of approximately 5.6. For this reason, acid precipitation is arbitrarily defined as precipitation with a pH value of less than 5.6. Natural sources of acid precipitation include geologic weathering, volcanic eruptions, anaerobic decomposition of organic matter, air-borne sea-salt sprays, and production of N oxides (NO_x) during lightning storms. The increased acid precipitation burden in recent decades has been attributed to anthropogenic sources that include combustion of fossil fuels (especially coal and oil), certain industrial processes (especially smelting of ores), exhausts from internal combustion engines, and N fertilizer application to agricultural and forest lands.

Widespread occurrence of acid precipitation (i.e., both wet and dry deposition) results in large part from industrial emissions of the oxides of S (SO_x) and N (NO_x). These compounds are transformed in the atmosphere to sulfuric and nitric acids (Table 1), which can be transported over great distances before deposition on vegetation, soils, surface waters, and building structures. The average annual ratio of sulfuric to nitric acids in North America is approximately 2:1, but nitric acid is becoming progressively important relative to sulfuric acid because of the installation of flue gas desulfurization (FGD) systems in coal-fired power stations. The major impact of acid precipitation has been on freshwater ecosystems, while its impact on terrestrial ecosystems is more controversial. Forest health may be one casualty of acid precipitation, but increasing tropospheric ozone may also be a factor in forest decline.

Elemental cycling

The most significant proton (H^+)-generating processes in soil are associated with the cycling of C, N, and S (Table 1) and these processes can be grouped into two main categories: plant-induced (i.e., uptake and assimilation) and soil-induced (i.e., transformation) processes.

In the case of the C cycle, the metabolism of photosynthates results in the synthesis of organic acids and, at the cytoplasmic pH of the plants (pH 7.2–7.4), some of the carboxyl groups of these acids dissociate to produce H^+ ions. Cytoplasmic pH regulation is generally achieved by transport of excess H^+ ions out of the cytoplasm. Some terrestrial plant species counteract the change in cytoplasm pH by excreting H^+ ions into the soil solution and, at the same time, taking in a nutrient basic cation to balance the charge.

Plants take up N in three main forms—as an anion (nitrate, NO_3^-), as a cation (ammonium, NH_4^+), or as a neutral N_2 molecule (N_2 fixation). Depending upon the form of N taken up and the mechanism of assimilation in the plant, excessive cation or anion uptake may occur. To maintain charge balance during the uptake process, H^+ , OH^- , or bicarbonate (HCO_3^-) ions must pass out of the root into the surrounding soil. While the uptake of NH_4^+ and N_2 fixation result in a net release of H^+ ions, uptake of NO_3^- can result in a net release of hydroxyl (OH^-) ions. In the case of N_2 fixation, acidity is generated even when no ionic species of N are taken up by the plant. This is because basic cations are imported into the legume in exchange for H^+ ions generated during C assimilation into carboxylic acids. The amount of H^+ ion released during N_2 fixation is a function of C assimilation, and therefore it depends mainly on the nature and amounts of amino and organic acids synthesized by the plant. When ammonium assimilation occurs in the root, deprotonation of NH_4^+ to R-NH_2 releases one mole of H^+ per mole of NH_4^+ (Eq. (3.6) in Table 1). When plants take up NO_3^- , the NO_3^- ion is first reduced to NH_4^+ , which is subsequently assimilated into amino acids. This NO_3^- reduction produces one mole of OH^- ion for every mole of NO_3^- reduced to NH_4^+ (Eq. (3.9) in Table 1).

Sulfate (SO_4^{2-}) is assimilated into sulfur-containing amino acids (cysteine, cystine, and methionine) in the form of sulfhydryl ($-\text{SH}$) groups. This reduction process produces two net moles of OH^- for each mole of S assimilated (Eq. (3.12) in Table 1). On decomposition of sulfhydryl-containing amino acids, two moles of H^+ ions are generated for each mole of $-\text{SH}$ oxidized to sulfate. Since plants require roughly 10 times less S than N, assimilation of SO_4^{2-} will have only a minor effect on the H^+ balance in plants.

As microorganisms decompose soil organic matter, they respire CO_2 , which upon hydrolysis forms H_2CO_3 (Eq. (3.1) in Table 1), eventually dissociating to H^+ and HCO_3^- ions (Eq. (3.2) in Table 1). The continuous production of CO_2 through soil and root respiration increases the concentration of CO_2 in the soil air spaces. Soil microorganisms also produce organic acids when they decompose plant litter that is rich in organic compounds but low in charge-balancing basic cations (Eq. (3.2) in Table 1). In general, conifer litter tends to produce more organic acids than does leaf fall from deciduous woodlands.

Nitrification and ammonia (NH_3) volatilization result in the release of H^+ ions. While the ammonification process (conversion of organic forms of N to $\text{NH}_4^+ - \text{N}$) results in the release of OH^- ions, the subsequent oxidation of NH_4^+ to NO_3^- (nitrification) results in the release of H^+ ions. Combined ammonification (Eq. (3.4) in Table 1) and nitrification (Eq. (3.8) in Table 1) of organic N compounds, including urea, in theory generates one net mole of H^+ for every mole of N transformed. In alkaline media NH_4^+ ions dissociate into gaseous NH_3 , which is subject to volatilization (Eq. (3.7) in Table 1), resulting in a net decrease in pH with the consumption of OH^- ions (or release of H^+ ions) as NH_4^+ is converted to NH_3 .

In aerobic soils, H^+ ions are produced during the mineralization and subsequent oxidation of S in soil organic matter (Eq. (3.11) in Table 1). As soil bacteria and fungi decompose plant litter and soil organic matter rich in C but low in S, soil solution SO_4^{2-} may be immobilized. In this case (Eq. (3.11) in Table 1) is reversed and it becomes an H^+ -consuming reaction, because SO_4^{2-} is assimilated into microbial biomass. Under anaerobic conditions, some bacteria have the capacity to use SO_4 as a terminal electron acceptor, resulting in H^+ consumption as SO_4^{2-} is reduced along a chain of intermediate compounds to hydrogen sulfide (H_2S). The

H₂S reacts with metal ions to precipitate as metal sulfides, which is an H⁺-consuming process. However, when these metal sulfides are reoxidized they generate H⁺, acidifying the soil (acid drainage).

Fertilizer reactions

Fertilizer application in ecosystems managed for agricultural production is a major contributor to soil acidification. The acidifying effects of fertilizers commonly used in agricultural production are presented in Table 2.

Application of N fertilizers such as urea and ammonium sulfate to soils produces H⁺ by two processes: nitrification (Eq. (3.8) in Table 1) and NO₃⁻ leaching. Part of the H⁺ produced is neutralized by OH⁻ released by plants during the subsequent uptake of the NO₃⁻ ions (Eq. (3.9) in Table 1). The depletion of basic cations (Ca, K (potassium), Mg, and Na) during the leaching of NO₃⁻ ions (i.e., as ion pair) and product removal (i.e., silage) accelerates the acidification process. In the case of ammonium sulfate, the concomitant leaching of SO₄²⁻ and NO₃⁻ ions causes greater depletion of basic cations. With urea, the initial conversion of amide N (R-NH₂) to NH₄⁺ (ammonification) releases OH⁻ (Eq. (3.5) in Table 1), which neutralizes part of the H⁺ produced during the subsequent oxidation of NH₄⁺ to NO₃⁻. This explains why urea-based N fertilizers are less acidifying than the NH₄⁺-based fertilizers (Table 2).

Superphosphates, the most common phosphate fertilizers, contain monocalcium phosphate (MCP) as the principal P component. Dissolution of MCP in soils results in the formation of dicalcium phosphate with the release of phosphoric acid, which subsequently dissociates into phosphate anions (H₂PO₄⁻) and H⁺. Part of H⁺ is subsequently neutralized by the OH⁻ released during the adsorption of H₂PO₄⁻ by soil particles. Compared with weakly adsorbed SO₄²⁻ and NO₃⁻ ions, H₂PO₄⁻-induced leaching of basic cations is unlikely to occur, because the H₂PO₄⁻ ions are strongly adsorbed by most soils.

In legume-based pasture and crop-production systems, P fertilizers are added to promote N₂ fixation by the legumes. Regardless of P fertilizer source, application of P to legume-based systems promotes N₂ fixation, thereby indirectly causing soil acidification. The amount of acidity produced indirectly by N₂ fixation depends mainly on the extent of NO₃⁻ leaching and it can be greater than that produced directly by the dissolution of MCP in superphosphate fertilizer granules (Table 2).

Elemental sulfur (S⁰) is used as an acidifying agent, as a slow-release S fertilizer or, in a finely divided form, as a fungicide. When S⁰ is added to soils, it is oxidized to sulfuric acid, which dissociates into SO₄²⁻ and H⁺ ions (Eq. (3.13) in Table 1).

Measurement and effects of soil acidity

The acidity of a soil is assessed from the activity of H⁺ ions in the soil solution. There is a huge range of [H⁺] in soil solution, therefore, a logarithmic scale (known as pH scale; pH = -log [H⁺]) is used to quantify acidity. In soils, acidification is indicated by a decrease in either pH or anion neutralizing capacity. For a given input of acidity, the extent to which pH decreases depends mainly on the pH buffering capacity of the soil. Various soil constituents, such as organic matter, Fe (iron) and Al oxides, and CaCO₃ (in calcareous soils) contribute to the pH buffering of soils at different pH values. Depending on organic matter content, texture, and

Table 2 Acidity production by various fertilizers and its effect on pH of two soils with contrasting buffer capacities.

Fertilizer	Acidity equivalence ^a	Acidity produced (kmol H ⁺ ha ⁻¹) ^b	Number of years required to reduce soil pH by 1 unit ^c	
			Tokomari silt loam	Egmont clay loam
Ammonium sulfate	110	2.60	8	26
Ammonium chloride	93			
Ammonium nitrate	60			
Diammonium phosphate	74	2.06	10	33
Monoammonium phosphate	55			
Urea	79	0.86	25	78
Potassium nitrate	-23			
Calcium nitrate	-50			
Sodium nitrate	-29			
Nitrogen fixation	70–250	–		
Single superphosphate	8	0.48	45	140
Triple superphosphate	15	0.50	43	135
North Carolina phosphate rock	-50			
Calcium sulfate	-57			
Potassium sulfate	-64			
Elemental sulfur (S ⁰)	310	1.55	14	43

^aAcidity equivalence is the number of parts by weight of pure lime (calcium carbonate) required to neutralize the acidity caused by 100 parts of the fertilizer. Negative values indicate the liming value (kilograms CaCO₃ 100 kg⁻¹) of the fertilizer.

^bAmmonium sulfate, diammonium phosphate, and urea added at the rate of 25 kg N ha⁻¹ year⁻¹; single and triple superphosphate at the rate of 30 kg P ha⁻¹ year⁻¹; and S⁰ at the rate of 30 kg S ha⁻¹ year⁻¹.

^cpH-buffering capacity (kilomoles H⁺ per hectare) of 21.7 and 67.5 for the Tokomaru and the Egmont soil, respectively.

the nature of the clay mineralogy, the amount of acidity needed to reduce the pH of topsoil (noncalcareous) by 1 unit is normally in the 1- to 8-cmol (H^+) kg^{-1} range. These values translate to buffer capacities of approximately 10–70 kmol (H^+) ha^{-1} for the top 7.5 cm soil layer. The amounts of acidity produced by selected fertilizers and the number of years required to reduce soil pH by 1 unit are shown in Table 2 for two soils with contrasting pH buffer capacities. It is clear that annual application of ammonium sulfate or ammonium phosphates could acidify soil within a short time (10 years), particularly when soil pH-buffering capacity is low.

Acidification affects the transformation and bio-geochemical cycling of both nutrients and metals through its effect on the physical, chemical, and biological characteristics of soils. Soil pH can be viewed as the master variable of all the controlling factors, because it can affect the surface charge and subsequent adsorption of solutes by variable-charge soil components. In addition to its effect on the sorption of metal cations and anions in soils, it also influences metal speciation, complexation of metals with organic matter, precipitation and dissolution reactions, redox reactions, mobility and leaching, dispersion of colloids and, ultimately, the bioavailability of trace metals.

Soil pH affects the surface charge through the supply of H^+ for adsorption on to the metal oxides and dissociation of the functional groups in the soil organic matter. A decrease in pH decreases the net negative charge (often referred to as cation exchange capacity or CEC) and increases the net positive charge (often referred to as anion exchange capacity or AEC).

Because acidity governs the type, number, and activity of microorganisms in soil, it influences the rate of organic matter mineralization and availability of elements such as N, S, and P. Because of suboptimal microbial activity in highly acid conditions, organic matter accumulates, giving rise to a storehouse of nutrients that can be exploited by liming. Likewise, nitrification is markedly reduced below pH 6, whereas the ammonification reaction is relatively insensitive to acidity, resulting in the accumulation of NH_4^+ in acidic soil where nitrification is inhibited. Thus, for certain crops unable to use NH_4^+ , acidification can result in restricted uptake of N and it may promote NH_4^+ toxicity.

Acidity has a deleterious effect on the symbiotic relationship between *Rhizobia* and legumes, and nodulation and N_2 fixation are generally poor below pH 6. Physiological reasons for this include:

- 1) inhibition of rhizobial infection of legume roots, decreasing nodule formation;
- 2) inhibition of nitrogenase enzyme activity in the nodule due to modification of the nitrogenase iron protein;
- 3) decrease in bacterial membrane potential and the inhibition of the leghemoglobin;
- 4) decrease in the supply of photosynthate to the rhizobium due to the poor supply of major nutrients, such as P; and
- 5) poor supply of Mo (molybdenum) and Ca, which are essential for N_2 fixation.

A decrease in soil pH will increase the concentrations of Fe and Al in soil solution and this may lead to adsorption or precipitation of phosphate. In variable-charge soils, a decrease in pH increases the AEC, which increases the retention of phosphate. However, at very low pH, solubilization of P compounds may result in an increase in the concentration of P in the soil solution. Under acid conditions, weathering liberates K from micaceous and feldspar minerals, enabling it to enter the soluble and exchangeable pools; but with? in variable-charge soils, increasing acidity decreases CEC, reducing the ability of the soil to retain K, and this may cause K to be more prone to leaching.

In many soils, organic matter is the main source of S and, since mineralization of organic matter may be slowed by acidity, the release of S for plant uptake may decline when soil is acidified. Furthermore, in highly weathered acid soils, SO_4^{2-} (sulfate) may be adsorbed by sesquioxide surfaces, precipitated as Al—OH—SO_4^- type minerals, such as alunite and basulminite, and or held as an exchangeable anion on positively charged sites on sesquioxides.

One of the major consequences of acidification is a decline in basic cations such as Ca^{2+} and Mg^{2+} , cations leading to potential deficiency of these cations for plant growth. Furthermore, at low pH, the bioavailability of Ca may be restricted due to antagonistic effects of soluble Al. With increasing soil acidification, smaller amounts of Mg^{2+} remain in exchangeable form because of a reduction in negative charge. Since Mg^{2+} is a poor competitor with Al^{3+} and Ca^{2+} for the exchange sites, it tends to accumulate in the solution phase and is therefore more prone to leaching.

Acidification affects the transformation of metal ions through: (1) changes in surface charge in variable-charge soils; (2) changes in metal speciation; and (3) shifts in the oxidation-reduction reactions of metals. In general, the solubility and phytoavailability of metals such as Cu (copper) and Zn (zinc) are inversely related to soil pH. Since Cu is largely complexed with humic substances, the greater solubility of humic compounds at high pH may result in more soluble Cu when pH is raised, although this organically complexed Cu might not have poor bioavailability. One of the major consequences of soil acidification is the increase in concentrations of soluble Al and Mn, both of which are highly toxic to plant growth. A primary aim of liming soils for agricultural production is to decrease the concentration of these elements. While Mn toxicity is directly related to the metabolic requirements of plants, the effect of Al toxicity appears to be largely manifested as malformation and malfunction of the root system, a syndrome which is exacerbated by small amounts of Ca in solution in acid soils.

Under acid conditions, boron (B) occurs in soil solution as the uncharged H_3BO_3 (boric acid) molecule and thus it is readily available in acid soil. Unlike other anions, Mo is highly insoluble in low pH conditions and it may become limiting when soil is acidified.

Cadmium (Cd) has been identified as a potential human health hazard, which enters the food chain through plant uptake. Adsorption of Cd^{2+} by soil decreases with decreasing pH for the following reasons: (1) in variable-charge soils, a decrease in pH results in a decrease in cation adsorption and (2) a decrease in soil pH is likely to result in an increase in free Cd^{2+} at the expense of the more strongly adsorbed hydroxy-cadmium species. In general, Cd uptake by plants increases with decreasing pH and consequently it is recommended that soil pH be maintained at pH 6.5 or greater in land receiving Cd-rich biosolids.

The effect of soil acidity on the adsorption of metalloids such as arsenic (As) and selenium (Se) is controlled by two interacting factors—pH-related changes in negative potential in the plane of adsorption and pH-induced changes in the amount of negatively charged ionic species present in soil solution. While the first factor results in a decrease in As(V) (arsenate) adsorption when pH is raised, the latter factor is likely to cause the opposite effect. Thus, the effect of pH on As(V) adsorption depends on the nature of the mineral surface. In soils with low oxide content, increasing the pH will have little effect on As(V) adsorption, while in highly oxidized soils, adsorption will decrease with increasing pH.

Amelioration of soil acidity

Three approaches can be taken to minimize the rate and impacts of soil acidification: (1) reduce the amount of H^+ ions generated, (2) minimize the extent to which the H^+ and OH^- ions generating processes are uncoupled, and (3) neutralize the acidity produced. In managed ecosystems, the rate of acid generation can be altered by applying nutrients in forms that produce less acidity, selecting plant species that accumulate less cation, and reduce the loss of C, N, and S from soil.

Traditionally, liming has been the most common practice used to alleviate soil acidification (Holland et al., 2018; Chen et al., 2018; Nguyen, 2023; Fageria and Baligar, 2008). A range of liming materials is available, including calcite ($CaCO_3$), burnt lime (CaO), slaked lime ($Ca(OH)_2$), dolomite ($CaMg(CO_3)_2$), and slag ($CaSiO_3$). Recently, the liming potential of other Ca-containing compounds has been evaluated. Some of these materials include phosphate rocks (PRs), FGD gypsum, fluidized bed boiler ash, fly ash, and lime-stabilized organic composts. The amount of liming material required to rectify soil acidity depends on the neutralizing value of the liming material and pH-buffering capacity of the soil.

Unlike soluble P fertilizers, PRs can have a liming value, because they contain some free $CaCO_3$, which itself can act as a liming agent and, secondly, the dissolution process of the P mineral component (i.e., apatite) consumes H^+ , thereby reducing the soil acidity. While the free $CaCO_3$ in PRs dissolves reasonably fast, providing a small, immediate liming effect, the apatite generally dissolves at a slower (but variable) rate and has liming value over a longer period of time.

Alkaline-stabilized biosolids are increasingly being used as agricultural lime substitutes and soil amendments. Alkaline stabilization of biosolids utilizes a combination of high pH, heat, and composting to kill pathogens and stabilize organic matter. A range of alkaline materials is used for this purpose, including cement-kiln dust, lime-kiln dust, lime, limestone, alkaline coal fly ash, FGD, other coal-burning ashes, and wood ash. To minimize metal mobility and bioavailability in biosolid-amended soils, the US Environmental Protection Agency (USEPA) recommends the application of alkaline-stabilized biosolids and other liming agents to increase the soil pH to 6.5 or more.

The primary purpose of liming arable soils is to overcome the chemical problems associated with soil acidity that include large concentrations of acid ions (H^+ and Al^{3+}) and toxic elements (Mn^{2+}), and small concentrations of basic cations (Ca and Mg), and other nutrient ions such as Mo and P. The hydrolysis of the basic cations in lime produces OH^- ions, which neutralize the H^+ ions, thereby decreasing the activity and bioavailability of Al and Mn. Liming also increases the solubility of Mo and P, thereby increasing their availability. Lime provides the basic nutrient cations (Ca^{2+} and Mg^{2+}) and also reduces the solubility of 'heavy' metals, thereby minimizing their bioavailability and mobility in soils.

Alkalinization can also be achieved by the application of biochars (Bolan et al., 2023). There has been considerable research on their uses in the last decade, often focused on tropical soils (Dai et al., 2017; Awad et al., 2018; Li et al., 2018; Basak et al., 2022). Among the advantages of the use of biochars over traditional liming materials is that they can be produced locally, and they are reputed to have other beneficial effects on soil fertility and physical structure.

In conclusion, there is a rather narrow pH range in fertile agricultural land. Various microbiological and chemical processes contribute to soil acidification and therefore management may be required to avoid excessive acidification.

Abstract

pH is undoubtedly the most important chemical soil characteristic that determines the chemical environment of higher plants and soil microbes. There are few reactions involving any component of the soil or of its biological inhabitants that are not sensitive to soil pH. This sensitivity must be recognized in any soil-management system. pH is defined. Some approaches to the measurement of soil pH are briefly described. The factors affecting pH and its measurement are discussed.

Key points

- pH is an important chemical property defining many chemical and biological processes.
- Soil pH measurement is subject to possible artefacts.
- Planar optodes allow spatio-temporal mapping of pH in soil.

Introduction

The acidity-alkalinity status of a soil is referred to as 'soil reaction,' which is often quantified by measuring soil pH. pH is considered to be the 'master variable' of a soil, which determines many of the physical (e.g., flocculation or deflocculation), chemical (e.g., adsorption or desorption), and biological (e.g., mineralization or immobilization) properties of soils. In this chapter, the fundamentals of soil pH will be discussed in relation to its measurement and practical implications.

Theoretical basis of pH

Pure water dissociates into the hydronium ion (H_3O^+), which is associated with acidity, and hydroxyl ion (OH^-), which is connected with alkalinity:

In aqueous media, the free acid cation is mostly present as the hydrated proton (H_3O^+) but for convenience it is often referred to as a hydrogen ion or proton (H^+), and thus the dissociation of water is often represented simply as:

This is a reversible reaction that obeys the law of mass action:

$$[\text{H}^+] \times [\text{OH}^-] / [\text{H}_2\text{O}] = K_w \quad (3)$$

where K_w is a constant and $[H^+]$ is the hydrogen ion concentration. Because the degree of dissociation of pure water is so small, the concentration of undissociated H_2O molecules always remains constant so that the product $[H^+] \times [OH^-]$ gives a constant value (K_w), known as the dissociation or ionization constant of water. The K_w value for pure water at 25 °C is 1×10^{-14} , with equal concentrations of H^+ and OH^- ions (1×10^{-7} M):

$$K_w = [H^+] [OH^-] = 1.0 \times 10^{-14} \quad (4)$$

If a chemical substance is added to water, which either donates or consumes H^+ or OH^- ions, then the concentration balance between H^+ and OH^- ions is disturbed. The numerical product of the concentrations must, however, remain constant so that if $[H^+]$ increases, $[OH^-]$ must decrease accordingly, and vice versa.

To simplify the arithmetical representation of Eq. (4), Sørensen suggested that the equilibrium state could be defined simply by reference to the $[H^+]$ and, to avoid the use of cumbersome decimal fractions, he proposed the use of a term designated 'pH' (French *pouvoir hydrogène* or *puissance d'hydrogène*, or 'hydrogen power') which is defined as the $\log_{10}$ of the reciprocal of the $[H^+]$ measured in Eq. (5):

$$pH = \log_{10} 1/H^+ \text{ or } -\log_{10}(H^+) \quad (5)$$

Expressing Eq. (4) as a negative logarithm yields:

$$pH + pOH = 14 \quad (6)$$

where pH and pOH are the negative logarithms of the H^+ and OH^- ion activities, respectively.

Thus, the pH of an aqueous solution is defined as the negative logarithm of the H^+ ion activity in the solution, which is the same as the $[H^+]$ when the salt concentration in the solution is very small. This concept can be applied to a system in which the individual molecules and ions are uniformly dispersed throughout the solution within the limits set by variations due to molecular and ionic thermal movements.

The pH scale ranges from 0 to 14, with pH 7 as the neutral point. At pH 7, $[H^+]$ equals the $[OH^-]$. From pH 7–0, the solution is increasingly more acidic; from pH 7–14, the solution is increasingly more alkaline (basic; Fig. 1). The $[H^+]$, which is the ion measured when determining pH, has a 10-fold change between each whole pH number. Thus, a solution with pH 5 will have 10 times more $[H^+]$ than a solution with pH 6.

Fig. 1 pH scale and the effect of pH on nutrient availability and microbial activity.

Measurement of pH

pH is commonly measured either electrometrically using potentiometers or colorimetrically using pH-sensitive dyes.

Potentiometric method

This method involves measurement of the potential difference between an electrode whose potential is determined by the $[H^+]$ of the solution and a reference electrode whose potential is independent of $[H^+]$. The normal hydrogen electrode is the glass electrode, and the reference electrode is a calomel electrode in which calomel ($HgCl_2$, mercury chloride) is bathed in a solution of potassium chloride (KCl) (Fig. 2).

The glass electrode consists of a thin glass bulb containing dilute HCl (hydrochloric acid), into which is inserted an Ag—AgCl (silver-silver chloride) wire, serving as the electrode with a fixed voltage. The HCl solution is separated from the test solution by a membrane of special glass, usually a lithium silicate of particular composition. Differences in H^+ activity across this membrane cause a difference in electrical potential, which can be measured by a potentiometer.

When the glass bulb is immersed in a solution, a potential difference develops between the solution in the bulb and that outside the bulb. The electrical potentials developed by this electrode are the membrane potential, plus the potential of the Ag—AgCl—HCl reaction inside the electrode:

This reaction is reversible and the Ag—AgCl potential ($E^0 = 0.222$ V at $25^\circ C$) is likely to remain constant. This potential is cancelled out when the electrode is standardized against a standard pH buffer solution.

The glass electrode develops a second potential at the membrane separating the standard HCl and the test solutions. The minute current flow required by the pH meter develops a double layer in the solutions, causes ion exchange at the inner and outer surfaces, and causes diffusion of ions across the glass membrane. The potentials across the glass membrane can be closely calibrated to the approximate value of the H^+ activity.

A typical reference electrode consists of a wire dipped into the liquid mercury, which makes electrical contact with the pH meter. Current flows from the electrode to the solution phase through the reversible reaction ($E = 0.268$ V at $25^\circ C$):

The Cl^- (chloride) activity is fixed by the KCl concentration (usually saturated KCl). As a result this potential also cancels out when the pH electrode system is standardized in a standard pH buffer. The KCl diffusion through the orifice makes the electrical contact between the reference cell and test solution. This KCl connection forms a 'salt bridge' between the test solution and the reference electrode. The reference electrode is often built in the same body as the glass electrode to form a combination electrode.

When measuring pH, the potential (E) in the glass electrode is formulated by the Nernst equation:

$$E = (RT/nF) \log(K/H^+) \quad (9)$$

where R is the gas constant, T the absolute temperature, n the valence, F the Faraday constant, K a constant, and H^+ the activity of H^+ ions. The E is called the 'half-cell potential' and cannot be measured alone. If the glass electrode is placed against a reference calomel electrode, the potential difference between the two ($E - E_{ref}$) is measurable.

Before any pH measurement, the two electrodes have to be calibrated using solutions of known pH. This is called 'standardizing' the electrodes and the pH meter. The overall potential of the total cell E_0 equals $E - E_{ref}$.

Fig. 2 Hydrogen (glass) and reference (calomel) electrodes. Reproduced from Tan KH (1998) *Principles of Soil Chemistry*. New York: Marcel Dekker.

$$E_0 = [(RT/F) \log(K/H_{\text{std}}^+)] - E_{\text{ref}} \quad (10)$$

If the two electrodes are now placed in the solution with the unknown $[H^+]$, the potential E_c is:

$$E_c = [(RT/F) \log H_{\text{test}}^+] - E_{\text{ref}} \quad (11)$$

Subtracting Eq. (10) from Eq. (11) gives:

$$E_c - E_0 = (RT/F) [\log H_{\text{test}}^+ - \log H_{\text{std}}^+] \quad (12)$$

$$E_c - E_0 = (RT/F) \log (H_{\text{test}}^+/H_{\text{std}}^+) \quad (13)$$

or

$$E_c - E_0 = (RT/F) (\text{pH}_{\text{std}}/\text{pH}_{\text{test}}) \quad (14)$$

where E is the measured potential and is converted to pH units by the scale of the pH meter. The E_{ref} includes all other potentials, which are nullified by standardizing the systems with a standard pH buffer solution.

Since $RT/F \approx 0.0591$ at 25°C :

$$\text{pH} = (E_c - E_0)/0.0591 \quad (15)$$

This means that for a change of 1 pH unit, the potential will change by 0.0591 V.

The glass electrode has a uniform response to a wide range of H^+ activities and is less sensitive to interfering ions. The extent of interference is denoted by the selectivity ratio, the concentration ratio of the test ion to interfering ion at which the interfering ion exerts a significant potential at the membrane. The selectivity ratio of the pH glass membrane for H^+ over Li^+ , the most serious interfering ion, is approximately 10^9 . That is, Li^+ would cause a significant pH error in a pH 9 solution containing $1 \text{ mol L}^{-1} Li^+$ or in a pH 10 solution containing $0.1 \text{ mol L}^{-1} Li^+$. The selectivity ratio for Na^+ , the next most serious interference, is approximately 10^{13} .

The miniaturization of pH electrodes has allowed pH to be measured directly in moist soil or gels containing soil. This can allow pH gradients or dynamics to be monitored. However this approach is limited by the fragility of glass electrodes in contact with abrasive soil particles.

Determination of pH using pH-sensitive dyes

Rapid measurement of pH can also be achieved colorimetrically with pH indicator dyes. Colorimetric methods are based on the change in color that takes place on the dissociation of a weak acid, or weak base organic dye; thus for a weak acid dye:

where raising the pH will cause a change in color as the undissociated dye (HI) changes to the dissociated form (I^-). Typically a mixture of dyes is used to yield color changes that take place over a wide range of pH values. However, the color can only be measured accurately in a solution from which the solid particles are removed; the color also depends on the concentration of various salts present in the solution. A dye solution is mixed with the solid to make a slurry, the dye is decanted and the color is visually compared with a color chart. The pH measured in this manner was considered to be less precise than the results obtained using the glass electrode.

Nevertheless much progress has been made with this approach. Indicators are often dissolved in gels allowing color intensity to be measured non-destructively using portable spectrometers. This makes the technique much more quantitative than a simple visual comparison of color and intensity. A variant on this is to place thin gels containing indicators on top of a layer of soil, in a manner analogous to X-ray film. The indicator is assumed to remain in the gel and be immobile. This gel technique is also used to obtain maps of soil catalytic activity; zymography. The application of optodes can avoid the problem of mobility of either indicator molecules of the proton or hydroxide couple within a porous gel. Optodes may be planar, like the gel film (Faget et al., 2013; Ma et al., 2019; Merl et al., 2022), although the earliest were fiber optics, used in the same way as a glass electrode (Motellier et al., 1995). The use of fluorescent imaging has further improved the sensitivity of this approach (Rudolph et al., 2013).

Measurement of soil pH

Because 'pH' is a term that is only defined for solution, in a strict sense, it cannot be applied to a solid-phase material such as soil. However, the chemical properties of the solid-phase components in soil define the pH of the soil solution (i.e., the solution in the soil pores). Further, the pH of a soil dispersed in water is not a simple concept like that of a solution. When soil particles, which carry ions attached to them, are dispersed in solution, the ions are not uniformly distributed throughout the solution. The concept of the pH of a soil (or soil suspension) can therefore only be discussed in relation to the properties of the ionic atmosphere around the soil particles (i.e., soil-solution interface).

When a negatively charged soil particle is dispersed in water, the negative charge is neutralized by cations, some of which sit firmly on the clay surface, forming the Stern layer, and some dissociate into the dispersion medium to form the Gouy diffuse double layer. The thickness of this double layer depends in part on the ions dissolved in the dispersion medium, and the thickness increases with a decrease in the concentration of the ions, a decrease in the valency of the cations, and an increase in the size of the cation. The $[H^+]$ in the solution surrounding the soil particles is less than that close to the soil particles due to the $[H^+]$ gradient in the double layer. As the double layer is made more compact by adding an electrolyte to the soil-water system, the $[H^+]$ gradient across the double layer is reduced, and the pH in the solution becomes almost equal to that close to the surface of the soil particle. Thus the pH of the bulk solution is greater than the pH just outside the Stern layer unless the salt concentration in the solution is large.

The pH of most soils ranges from 3 to 8.5. Soils do not normally have a pH below 3–4 unless they contain free acids (e.g., acid sulfate soils and acid mine drainage). Similarly soils normally only have a pH >8.45 if they contain enough exchangeable sodium (i.e., alkali soils). Further, in calcareous and alkali soils, the effective pH around plant roots can be determined by the concentration of carbon dioxide (CO_2) produced during respiration by roots and microorganisms.

Strictly, the pH of a soil should refer to the $[H^+]$ in the soil solution. This is very difficult to measure, and hence soil pH is often referred to measurements made in the soil suspension. Three common, standard methods for determining pH in soils involve the suspension in distilled water, 0.01 mol L⁻¹ $CaCl_2$, or 1 mol L⁻¹ KCl solutions at a soil-to-solution (weight-to-volume) ratio of 1:1, 1:2.5 or 1:5 (recommendations vary between countries).

The pH of a solution in equilibrium with a soil varies with the composition and concentration of the salts in the solution. This is because cations in solution displace H^+ and Al^{3+} ions from soil surfaces. The measurement of soil pH in a water extract is expected to be higher than the pH of the soil solution of natural soil water contents. The excess quantity of water added to prepare the suspension results in a dilution of the salts in the soil solution. Since soils always contain some soluble salts, such as nitrates and chlorides, the apparent pH of the soil will depend on the amount of water added to the soil to make the suspension. Further, the amount of soluble salts in a soil varies continuously throughout the season, depending on factors such as the amount of drainage water percolating through the soil.

Soil pH values measured in 0.01 mol L⁻¹ $CaCl_2$ or 1 mol L⁻¹ KCl salt solutions are generally less than those obtained using water, because the cations in these salts tend to displace H^+ and Al^{3+} from soil materials to the soil solution. These salt solutions are sufficiently concentrated to overwhelm variations in salt concentration in soil solution, thereby minimizing the effect of salt concentration on pH in most soils. These solutions also eliminate the junction potential effect. Calcium is used in the determination of pH because it is the predominant soil solution cation in soils of temperate regions. The 0.01 mol L⁻¹ concentration, however, is somewhat higher than that found in most soil solutions, and thus the pH values obtained by this method are usually lower than the values of soil solutions.

For some subsurface horizons of highly weathered soils of the tropics, pH in the salt solution can actually be greater than pH in water, especially in subsoils that are low in permanent-charge silicate clays and organic matter. Ion exchange in these soils is dominated by oxides and hydroxides of Fe and Al, and at acid pH values they are net positively charged, creating an effective sink for anion adsorption. Thus, on salt addition (i.e., $CaCl_2$ or KCl) more OH^- is displaced by Cl^- than H^+ by cations, resulting in an increase in pH.

Factors affecting soil pH

The pH of a soil is affected by the concentration of CO_2 in the soil air, salt concentration (salt effect), and the presence of colloidal particles (suspension effect).

Carbon dioxide

The larger the CO_2 concentration in the soil solution, the lower the pH; the pH of a neutral or calcareous soil is very sensitive to small changes in CO_2 concentration. In calcareous soils, its magnitude can be calculated from the solubility of calcium carbonate and CO_2 in water, because in such soils the pH is determined by the system, calcium carbonate-carbon dioxide-water, which is given approximately by:

$$2pH = K + pCa + pCO_2 \quad (17)$$

where pCO_2 is the negative logarithm of the partial pressure of CO_2 in equilibrium with the solution, pCa the negative logarithm of the activity of the calcium ions, and K is a constant whose value lies between 10 and 10.5, depending on the value used for the solubility constant of calcium carbonate. The decrease in pH is therefore approximately proportional to the logarithm of the partial pressure of CO_2 .

Thus, the pH of a well-aerated calcareous soil containing exchangeable sodium or magnesium ions cannot exceed approximately 8.5 when in equilibrium with the atmosphere; but if the CO_2 concentration rises to 0.1% (i.e., a small value for most soils) the pH drops to 8, and if it rises to 1% (a common value for pasture soils) the pH will be less than 7.5. Many plants suffer from phosphate and minor element deficiencies if the pH rises much above 8, and hence they can only thrive on calcareous soils if they can maintain

an adequate concentration of CO_2 around their roots. This is more easily achieved in soils of low porosity, such as clays, than in soils of high porosity, such as well-drained sands, and in organic matter-rich pasture soils than in organic matter-depleted arable soils.

Salt effect

As discussed above, the pH of a soil depends on the salt concentration in the soil solution. This dependence of measured soil pH on salt concentration can be reduced by making all the measurements in a salt solution that is sufficiently strong to swamp the effects of the changes that occur naturally. But adding a salt solution to the soil will cause cation exchange to take place and, in particular, exchange of H^+ ions from clay surface with the cation of the added salt, which will give a pH that is lower than the soil pH under normal conditions. The added salt solution should therefore cause as little exchange as possible, and the use of 0.01 mol L^{-1} CaCl_2 or 1 mol L^{-1} KCl solution has been proposed for most arable soils on the grounds that they approximate the salt concentration in the soil solution and do not give appreciable junction potential with the calomel electrode. The pH of a soil measured in these solutions is more constant and is much less dependent on the soil-to-solution ratio than the pH measured in a water suspension, and it is also presumably closer to the pH of the solution around the plant roots.

Suspension effect

The difference in pH values between the suspension and its equilibrium solution is referred to as the 'suspension effect,' and this effect is identical to the Donnan e.m.f.

The electrode portion of a pH measurement circuit is presented in Fig. 3, where each vertical bar represents a phase boundary and the double bar represents the liquid-liquid junction. Thus, very appreciable junction potentials can be created between a soil suspension and the calomel electrode so that the measured potential difference between the two electrodes cannot be interpreted solely in terms of the $[\text{H}^+]$ outside the glass electrode.

A junction or diffusion potential always develops when two dissimilar substances or solutions of different composition come into contact. It is inevitable that a diffusion potential is created at the liquid junction between a salt bridge and a solution of different composition. An example in this case is the saturated KCl of the reference electrode diffusing into the test solution. At liquid junctions, differences in the mobilities of the cation and anion create a diffusion potential which is also influenced by any differences in the ion activities that exist across the junction. The potential is minimal when the rates of K^+ and Cl^- diffusion into the test solution are equal. It is therefore appropriate that an electrolyte in which the mobilities of the cation and anion are almost identical is used in the salt bridge. Indeed, KCl is used as the reference-cell electrolyte because of the similarity of K^+ and Cl^- diffusion rates in water. Because the current at the liquid junction is mainly carried by K^+ and Cl^- ions, which have similar diffusion coefficients, the liquid junction potential should be small. As long as the ionic strengths of the standard and unknown solutions are small compared with the concentrated KCl salt bridge solution, any liquid junction potential should, as well as being small, tend to be rather constant in magnitude and hence can usually be ignored.

Because factors involved in the liquid junction potential during pH calibration and subsequent pH measurement are likely to be different, the liquid junction potential contribution to the total e.m.f. of a cell will also be different. In a colloidal suspension, however, the colloid may cause K^+ and Cl^- to diffuse at different rates. Because of attraction and repulsion by the charged colloid, one ion moves ahead of the other. When a salt bridge makes contact through a suspension instead of clear solution, the situation is complicated by a reduced mobility of counter ions which arises from retarding effects created by the oppositely charged colloidal particles. This means that liquid junction potentials (E_j) are likely to be much greater in suspensions than in supernatant liquids. Accurate pH measurements require a negligible E_j , because such potentials are virtually unpredictable. The potentiometer measures all the potentials of the circuit and cannot distinguish between the H^+ ion potential at the glass membrane and the spurious E_j . The value of E_j at the interface between saturated KCl and a colloidal suspension of very small salt concentration can be as high as 240 mV, equivalent to more than 4 pH units (1 pH unit 59 mV). However, values of E_j greater than 30 mV are uncommon in soils, because salt concentrations in even highly leached soils are large enough to suppress E_j . Therefore measuring pH in salt solutions of 0.01 mol L^{-1} or more virtually eliminates E_j .

Suspension effects can be reduced by introducing the liquid junction of the reference electrode into clear supernatant liquid and not into the suspension. The rates of K^+ and Cl^- diffusion are then unaffected by soil colloid particles. The pH glass electrode, on the other hand, can be placed either in the supernatant solution or in the colloidal suspension. The H^+ activity is the same in both phases, and the glass electrode is unaffected by the presence of the colloid. However, it has been suggested that when measuring soil pH the glass electrode should be in the suspension on the basis that the suspension is better buffered than the supernatant liquid.

Fig. 3 The electrode portion of a pH measurement circuit.

Importance of soil pH

The soil pH is considered the ‘master variable’ which controls many other soil properties (Fig. 1). It greatly affects the solubility of minerals in soils. Most minerals are more soluble in acid soils than in neutral or slightly basic solutions. A low pH may indicate the deficiency of basic cations such as Ca^{2+} and Mg^{2+} in soils. Under acid soil conditions, the concentration of most ‘heavy’ metals, such as lead, cadmium, and mercury, reach phytotoxic levels. Strongly acidic soils usually have large and toxic concentrations of soluble aluminum and manganese. Azaleas (genus *Rhododendron*), tea (*Camellia sinensis* (L.) Kuntze), rhododendrons (*Rhododendron* L.), cranberries (*Vaccinium macrocarpon* Alton 1789), pineapple (*Ananas comosus* (L.) Merr.), blueberries (*Vaccinium* sect. *Cyanococcus* Rydb.), and several conifer timber species tolerate acidity and grow well in acid soils. In contrast, alfalfa (*Medicago sativa* L.), beans (*Phaseolus vulgaris* L.), barley (*Hordeum vulgare* L.), and sugarbeets (*Beta vulgaris* L.) grow well only in slightly acidic to moderately basic soils because of a high calcium demand to tolerate soluble aluminum.

Soil pH can also influence plant growth through its effect on beneficial microorganisms. For example, most nitrogen-fixing legume bacteria are not very active in strongly acidic soils. Bacteria that decompose soil organic matter and thus release nitrogen and other nutrients for plant use are also hindered by strong acidity. Similarly, earthworms are not active in acid soils, whereas fungi usually tolerate acidity better than do other microbes.

Soil alkalinity, although more difficult to manage than soil acidity, may also be undesirable for plants. Alkaline soils may reach pH values of more than 10 with increasing levels of exchangeable sodium. Plants on soils with $\text{pH} > 9$ usually have reduced growth or even die. Some plants (halophytes) can tolerate large salt concentrations or high pH. Soluble $\text{Al}(\text{OH})_4^-$ may exist at these high pH values and is also toxic to plants. The major effect of basic pH is to reduce the solubility of all micronutrients (except chlorine (Cl), boron (B), and molybdenum (Mo)), especially those of iron (Fe), zinc (Zn), copper (Cu), and manganese (Mn). Also, phosphate is often not readily available to some plants because of its precipitation in the soil solution by calcium or precipitation on solid calcium carbonate. Iron deficiency, associated with soils high in carbonates, has long been known, and is referred to as ‘lime-induced iron chlorosis.’

Summary

Soil pH is one of the most important chemical properties that control many other soil physical, chemical, and biological properties. The pH of a soil depends on the CO_2 concentration in the soil air and the salt concentration in the soil solution, and these are constantly changing. Dynamic measurements using planar optodes allow new insights into pH gradients and dynamics in soils, particularly in zones such as the rhizosphere.

Abstract

Buffering is the capacity to resist changes and involves mineralogical, chemical and biological processes. Some soil ecological concepts are discussed. Most of this contribution focuses on pH-buffering in soils. The roles of minerals and organic matter in maintaining soil pH are discussed. The buffering of oxido-reduction (redox) status of soils is briefly presented.

Key points

- Buffer capacity is the capacity to resist change.
- The term is predominantly used in chemistry to describe pH-buffering.
- In soil science nutrient buffering, especially for potassium and phosphate, is an important concept.
- Buffering has been used to consider the resilience of ecosystems in ecology.

Introduction

Buffering is the resistance of a system to change in response to a perturbation, and it is a key attribute of soils from the molecular level to the landscape scale. Chemical, physical, and biological processes may raise or lower solute concentrations (or activities) as intensive variables in soil solution, thereby temporarily disturbing dynamic equilibria or steady-state conditions between soil water and solid or gas phases of the soil. In response to such a perturbation, one or more processes may release solute to soil solution or remove it to restore wholly or partially the original concentration. The reservoir of such solutes in solution, in solid phases, or in the soil atmosphere for restoration of soil solution chemical composition is known as the ‘capacity factor.’ The measurable change in the capacity factor per unit change in the intensive variable is called the ‘buffer index,’ ‘buffer intensity,’ or, more commonly, ‘buffer capacity.’ Myriad chemical reactions (buffering mechanisms) govern such release or uptake of ions and molecules between soil solution and solid or gas phases, including cation and anion exchange, oxidation-reduction reactions, dissolution-precipitation processes, and metal-organic ligand complexation. Understanding and quantifying buffer capacities and buffering mechanisms at the colloid and molecular level of soils can aid in predicting the sensitivity and resilience of soil-water systems to anthropogenic and natural perturbations of ecosystems.

In soil science buffer capacity of pH (Zhuang et al., 2006; Bloom and Skjellberg, 2011) and some major nutrients (Evangelou et al., 1994; Nair, 2013; Barrow, 2015; Barrow, 2022; Nair, 2022; Certini and Scalenghe, 2023) have been studied for decades. More recently the concept is considered for carbon (C) sequestration (Xu et al., 2020) and ecology (Trabelsi and Mhamdi, 2013; Doody et al., 2016; Certini and Scalenghe, 2023).

Ecological theory related to succession dynamics of disturbed ecosystems identifies that natural systems, including soils, are constantly and naturally recovering from regular and irregular disturbances of various severities. The processes and mechanisms of

recovery determine the biodiversity and stability of ecosystems, and buffering in soils and natural waters is a key control of nutrient availability and pollutant bioavailability. Buffering reactions influence water quality and community regrowth, migration, and recruitment in disturbed patches on the landscape. The success of human efforts to restore disturbed ecosystems and soils is also determined in part by the scale and nature of soil-buffering processes, as related to natural ones that govern element transformations.

The samovar analogy for buffering in soils

Concepts of the intensive variable, capacity factor, buffer capacity, and buffering mechanisms for soils can be modeled and visualized by analogy with old-fashioned Russian samovars used to make large volumes of tea (Fig. 1). Each samovar comprises a large copper reservoir to boil water and a narrow glass tube on the outside of the samovar's tank to indicate how full the tank is. As boiling water is drawn out of the tank through the spigot, the indicator tube empties quickly and temporarily, but is refilled to the new tank level when the spigot is shut off (as indicated by the arrows between the tank and indicator tube in Fig. 1). To decrease the volume of a samovar tank by a given fraction of its total capacity (e.g., from level 1 to level 2 in the indicator tube), a greater volume of water must be withdrawn from the larger samovar than from the smaller one.

Since the level of water in the indicator tube is proportional to how full each tank is, it is independent of the volume of the samovar. The height of the water column is analogous to an intensive variable in soil solution such as pH, a measure of how acidic an aqueous sample is, but not an indicator of its volume. The volume of the samovar represents the capacity factor (e.g., total soil acidity), and the change in the tank volume per unit change in the level of the indicator tube is the buffer capacity. Restoration of the water level in the indicator tube from the samovar after shutting off the spigot is due simply to the flow of water, i.e., the buffering mechanism in this model.

In this simple comparison of two samovars of different volumes, but with identical fractions of their capacities filled with water, as the boiling water is drained completely, the buffer capacity (change in tank volume per change in water level) remains constant. In complex soil colloid-water systems, however, buffer capacities do not usually remain constant as an intensive variable is changed, and the magnitude of the buffer capacity will change accordingly. This is modeled by a peculiar samovar with a narrow middle section and wide sections at the top and bottom (Fig. 2). In this samovar model, the system would be well buffered at the beginning and end of draining the tank, but would be poorly buffered in the middle. In soils, measurements of intensive variables are often made routinely (e.g., pH, Ca concentration, partial pressure of O_2 , and oxidation-reduction potential), and are used to indicate the energy state or 'ability of the system to do work' in affecting other coupled systems such as groundwater or plants rooted in the soil.

The size of the capacity factor and buffering mechanisms linking the intensive and capacity parameters are often not known with the same accuracy as are measurements of intensive variables in soils (i.e., the samovar tank is invisible). Therefore, investigations of the nature and scale of buffering processes in soils are needed to understand controls on the value of an intensive variable and what chemical and biological processes control its resistance to change.

Fig. 1 Samovar models representing small and large buffer capacities (tank sizes) in equilibrium with the same level of intensity variable (represented by the height of liquid in the narrow indicator tube outside the tank). Adapted from Brady NC and Weil RR (2002) *The Nature and Properties of Soils*, 13th edn. Upper Saddle River, NJ: Prentice-Hall.

Fig. 2 Samovar models representing small and large buffer capacities (tank sizes) in equilibrium with the same level of intensity variable (represented by the height of liquid in the narrow indicator tube outside the tank). The larger tank with the hourglass shape models a buffered system in which the buffer capacity (change in tank volume per unit change in the height of the liquid in the indicator tube) is not constant and varies during titration (drainage of the tank). Adapted from Brady NC and Weil RR (2002) *The Nature and Properties of Soils*, 13th edn. Upper Saddle River, NJ: Prentice-Hall.

The samovar analogy for soil buffering will be used to explain similarities and differences among several soil chemical processes responsible for the buffering of soil acidity, oxidation-reduction status, and metal ion activities controlled by dissolution-precipitation and organic complexation by ligands. Soil acidity and oxidation-reduction status of soils are considered master variables that control the steady-state chemical composition of soils and kinetics of the approach to chemical equilibrium. As a result, predicting their resistance to change in response to disturbance of soil conditions is relevant to many environmental quality, plant nutrition, and human health effects of soils. Dissolution and precipitation reactions are important in weathering, soil development, and leaching processes, and also in controlling nutrient and pollutant solubility, speciation, bioavailability, and cellular absorption. Organic and inorganic ligand complexation, typically of cations, controls ion activity in equilibrium with soluble and insoluble forms of the element. Each of these processes is a coupling of an ion activity (intensive variable), a capacity factor (reserve of ion), and a buffering capacity and buffering mechanism that govern how the intensity and capacity factors interrelate in a soil system.

Buffering of soil acidity

The intensive variable for soil acidity is conceptually defined as the hydrogen ion activity of soil pore water or 'active acidity,' and is operationally defined by measuring pH in a soil-water or dilute salt suspension with a glass-reference electrode system, where pH is $-\log(H^+)$ and (H^+) is the hydrogen ion or proton activity in units of moles per liter. To neutralize the active acidity (e.g., raising pH from 5.0 to 7.0) in the soil solution of the top 15 cm of a hectare of loamy soil at field capacity moisture (-10 kPa water potential) containing 200 g montmorillonite and 30 g organic matter per kilogram of soil would require approximately 500 g of $CaCO_3$. This is just a handful of lime, compared with the $10,000 \text{ kg } CaCO_3 \text{ ha}^{-1}$ that might be needed to raise the whole soil pH to 7.0. The 20,000:1 ratio of lime needed to neutralize the capacity factor or 'reserve acidity' of the soil to that needed to neutralize the active acidity reflects the relative size of the metaphorical samovar tank and its indicator tube for soil acidity.

Soil properties that determine the buffer capacity for soil pH include initial pH, aluminosilicate clay content, and mineralogy; organic-matter content; and $Al(III)$, $Fe(III)$, and $Mn(III,IV)(hydr)oxide$ contents. Soil pH buffer capacity is determined by adding increasing quantities of acid or base to a given mass of soil and measuring pH after allowing sufficient equilibration time for pH to stabilize. It is often designated:

$$\beta = dC/dpH \quad (1)$$

where β is the buffer index or capacity in units of moles of H^+ or OH^- added per kilogram of soil (dC) per unit pH change, dpH. The buffer capacity is quantified as the reciprocal of the slope of a linear relationship between measured pH plotted on the ordinate versus moles of H^+ or OH^- added per kilogram of soil on the abscissa.

Other, quicker indicator tests for reserve or total acidity as the capacity factor have been developed to estimate 'lime requirement' for acidic agricultural soils used to grow crops that are sensitive to acid soil conditions. Examples of these ways to estimate reserve acidity include chemical extractions of exchangeable and reactive Al^{3+} , measures of cation exchange capacity (CEC) and the fraction

of exchange sites occupied by 'basic' cations (predominantly Ca^{2+} (calcium), Mg^{2+} (magnesium), K^+ (potassium), and Na^+ (sodium)), measurements of decreases in the pH of well-buffered solutions added to the soil sample, and equilibrations of a soil sample with a BaCl_2 (barium chloride) solution buffered at pH 8.2, followed by titration to pH 5 to determine the quantity of acid that reacted with the buffer. Measurements of free CaCO_3 (calcium carbonate) content can be used to estimate the total alkalinity of a soil and its buffer capacity against acidification.

Diverse chemical reactions occurring on colloid surfaces of clay, oxides, and organic matter are responsible for pH buffering. They involve cation exchange reactions, dissolution and precipitation of sparingly soluble compounds, and surface charge changes in response to pH. In most soils, pH buffer capacity and buffering mechanisms are due to combinations of these reactions, and titrations and quick tests for total acidity do not distinguish between them. Nevertheless, understanding the relative importance of these processes and their chemical basis allows predictions of the buffering behavior of diverse soils, and it enables extrapolation to unstudied soil systems and environments, particularly related to ecological processes, soil contamination, and soil remediation.

Dissolution and precipitation of CaCO_3 and $\text{Al}(\text{OH})_3$

Soils containing free CaCO_3 have a pH between 7.0 and 9.5 (typically 8.0–8.5) as governed by the dissolution and precipitation of CaCO_3 in water containing partial pressures of CO_2 as high as 10 times that of atmospheric levels. Acidity produced by the hydration of dissolved CO_2 and by other acid-generating reactions reacts with CaCO_3 in accordance with:

In the presence of large concentrations of soluble or exchangeable Mg^{2+} or Na^+ , soluble MgCO_3 (magnesium carbonate) or Na_2CO_3 (sodium carbonate) will form and allow the soil pH to rise to values higher than that controlled by CaCO_3 – CO_2 equilibria (sometimes to pH >10). Addition of base or acid will be buffered by the lime in the soil, thereby maintaining its pH at approximately 8.2.

Under strongly acid soil conditions, Al^{3+} in soil solution and on cation exchange sites hydrolyzes and generates acidity, while the dissolution of $\text{Al}(\text{OH})_3$ (aluminum hydroxide) neutralizes it, leading to large β values at pHs <4.5:

Soluble and exchangeable Al^{3+} is released from aluminosilicate clays upon weathering of Si-dominated tetrahedral sheets (releasing soluble monosilicic acid, $\text{Si}(\text{OH})_4$), thereby exposing Al-dominated octahedral sheets to H^+ attack. As a result, the buffer capacity of strongly acid soils (pH <5) is dominated by Al chemistry.

Cation exchange reactions and pH buffering

In the intermediate pH range between 4.5 and 6.5, cation exchange reactions on permanent aluminosilicate cation exchange sites, and on pH-dependent sites of organic matter and (hydr)oxides govern the uptake and release of H^+ and OH^- as controls on the buffering-capacity size and mechanism for pH control. Permanent, negatively charged cation exchange sites on aluminosilicate clay minerals are due to isomorphous substitution of lower charge cations for Si^{4+} (e.g., Al^{3+}) in tetrahedral sheets and for Al^{3+} (e.g., Mg^{2+} and Fe^{2+}) in octahedral positions. Cation exchange sites created in this way during clay mineral formation are dominated by Ca^{2+} at and above pH 7 and become increasingly satisfied by H^+ and Al^{3+} at lower pH values. In this way, the so-called base saturation (an intensive variable reflecting the fullness of the acidity samovar) decreases as exchange sites are occupied by Al^{3+} and H^+ .

Organic matter functional groups (principally carboxylic acids, represented by $\text{R}-\text{COOH}$, and phenolic acid groups, such as $-\text{OH}$ on aromatic rings) are weak acids with association constants (pK_a s) in the range of 2–7 for carboxylic acids and 7–10 for phenolic acid groups. These groups deprotonate at pHs > pK_a , and protonate at pHs < pK_a . When $\text{pH} = \text{pK}_a$, maximal pH buffering is observed. The complexity of humic and fulvic acid molecular aggregates and functional groups leads to overlapping pK_a s that are not independent and which change as adjacent groups are protonated or deprotonated. In addition, conformational changes in the folding patterns of humic acid polymers as the suite of cations changes during titration result in changeable pK_a s for the cation exchange sites responsible for pH buffering. As a result, titration curves of soil organic matter are often linear and do not reflect sharp inflection points characteristic of mono- or poly-protic simple organic acid titration curves. In addition to exchange reactions on organic acids between H^+ , Al^{3+} , and Ca^{2+} , some precipitates, such as calcium oxalate, may exist in organic matter-rich horizons, such as in forest soils. These Ca-organic C precipitates may contribute to pH buffering through dissolution and precipitation reactions similar to those of CaCO_3 , but at soil pHs <4.

pH-dependent surface charge and pH buffering

Oxide and hydroxide coatings of Fe(III), Mn(III,IV), and Al on sand, silt, and clay minerals are dominated by oxygen- and hydroxide-rich planes exposed to soil solution, and changes in pH protonate and deprotonate these functional groups, thereby creating variable or pH-dependent charge colloid surfaces that contribute to buffer capacity:

where Me(III) represents a trivalent metal structurally associated with the mineral surface, and the charges on the surface become increasingly negative as pH is raised. Highly weathered soils that contain few aluminosilicate clay minerals or organic matter are often dominated by these variably-charged colloids, and they contribute to pH buffering through positive- and negative-charge creation.

The relative importance of CaCO₃ dissolution and precipitation, Al hydrolysis, cation exchange on permanently charged aluminosilicate minerals, organic-matter functional group protonation and deprotonation, and variation in negative and positive charges on variably-charged oxide coatings depend on the relative abundance of these colloids in a given soil. In many soils, more than one of these soil chemical processes is responsible for pH buffering, and titrations of whole-soil materials reflect an integration of the several processes. Table 1 summarizes the relative magnitudes of the buffer capacities associated with these processes.

Buffering of soil oxidation-reduction status

The concept of ‘electron activity’ of soils refers to the thermodynamic tendency for electrons to be transferred from reductants (e.g., Fe(II)) to oxidants (e.g., O₂), and it is operationally defined by platinum (Pt) electrode potentials versus a standard reference electrode. When the measured potential is corrected for the reference electrode potential relative to the hydrogen electrode ($E^0 = 0.0$ V), it is designated E_h . This voltage can be converted to pE, a property analogous to pH, by dividing E_h in volts by 0.059 (the Nernstian slope factor relating electrode voltage to electron activity). The E_h or pE is the intensity variable that is a measure of electron activity or ‘electron pressure’ in a soil system. Buffering of electron activity is called poise, and is analogous to proton buffering, except that the processes responsible for resistance to change in pE are due to electron transfer reactions, many of which are microbial and enzymatically catalyzed.

Heterotrophic microbial respiration in soils uses organic C as the electron source (reductant) and an array of electron acceptors as oxidants. Strict aerobes use dissolved oxygen (O₂) as the required oxidant to derive energy from the oxidation of organic C, the most energy-efficient process for cellular respiration. In flooded soils in which all pores are filled with water, the diffusion rate for dissolved O₂ is 10,000 times slower than it is in air. As a result, microbial respiration may deplete available O₂ faster than it is replenished, thereby leading to the onset of anaerobic conditions, with a decrease in the measured pE. Under anaerobic conditions, facultative anaerobes and strict anaerobes use alternative electron acceptors, with decreasing metabolic efficiency in the order (depending on pH): NO₃⁻, Mn(III,IV)(hydr)oxides, Fe(III)(hydr)oxides, SO₄²⁻, CO₂, and H⁺.

The quantities of each of these electron acceptors (the capacity factor for electron activity) in the soil will ‘poise’ the E_h at a given level as governed by the free energy of reaction associated with its reduction, as coupled to the oxidation of organic C. The expected pE and E_h values at which each of these couples would poise the soil are shown at pH 5 and 7 in Table 2. Since the molecular

Table 1 Approximate buffer capacities of soil materials and horizons in the pH range 3.0–10.0.

Soil constituent or horizon	Buffering pH range	Buffering index (mmol kg ⁻¹ pH unit ⁻¹)	pH-buffering mechanism
Aluminosilicate clays	3–10		
Smectite	3–10	178–333	Cation exchange; mineral dissolution/precipitation; Al hydrolysis
Vermiculite	3–10	333–444	Cation exchange; mineral dissolution/precipitation; Al hydrolysis
Illite	3–10	44–88	Cation exchange; mineral dissolution/precipitation; Al hydrolysis
Kaolinite	3–10	2–11	Cation exchange; mineral dissolution/precipitation; Al hydrolysis
Soil organic matter	5–8	360–444	Protonation-deprotonation of weak acid functional groups; conformational changes
Allophane and imogolite	3–10	44–111	Protonation-deprotonation of weak acid functional groups; conformational changes
Fe(III) and Al(III) (hydr) oxides	3–10	11–89	Protonation-deprotonation of weak acid functional groups; conformational changes
CaCO ₃ and MgCO ₃	<7	4444	Dissolution/precipitation
Forest floor organic horizons	3–7	180–360	Metal-ligand complexation/decomplexation; cation exchange; protonation/deprotonation; of weak acid functional groups
Mineral horizons of agricultural and forest soils	4–10	53	Cation exchange, mineral dissolution/precipitation, Al hydrolysis, protonation-deprotonation of weak acid functional groups, conformational changes, and metal-ligand complexation/decomplexation; principally associated with soil organic matter

Table 2 Common reduction half-reactions that poise soils at designated pE values at pH 5 and 7; the log *K* value is the pE for the reaction at pH 0.

Half-reaction (for 1 electron reduction)	log <i>K</i>	Poising pE	
		pH 5	pH 7
$1/4\text{O}_2 + \text{e}^- + \text{H}^+ = 1/2\text{H}_2\text{O}$	20.8	15.6	13.6
$+ \text{e}^- + 6/5\text{H}^+ = 1/10\text{N}_2 + 3/5\text{H}_2\text{O}$	21.1	14.3	11.9
$1/2\text{Mn}_3\text{O}_4 + \text{e}^- + 4\text{H}^+ = 3/2\text{Mn}^{2+} + 2\text{H}_2\text{O}$	30.7	16.7	8.7
$\text{Fe}(\text{OH})_3 + \text{e}^- + 3\text{H}^+ = \text{Fe}^{2+} + 3\text{H}_2\text{O}$	15.8	4.8	-1.2
$+ \text{e}^- + 5/4\text{H}^+ = 1/8\text{H}_2\text{S} + 1/2\text{H}_2\text{O}$	5.2	-1.0	-3.5
$1/8\text{CO}_2 + \text{e}^- + \text{H}^+ = 1/8\text{CH}_4 + 1/4\text{H}_2\text{O}$	2.9	-2.1	-4.1
$\text{e}^- + \text{H}^+ = 1/2\text{H}_2$	0	-5	-7
$1/4\text{CO}_2 + \text{e}^- + \text{H}^+ = 1/24\text{C}_6\text{H}_{12}\text{O}_6 + 1/4\text{H}_2\text{O}$	-0.21	-5.9	-7.9

reaction mechanism for many reduction reactions involves transfer of the electron with a proton to the oxidant (equivalent to the addition of a H atom), the overall reaction raises the soil pH in many cases. As a result, the higher the pH of a soil, the lower the E_h or pE at which a given reduction reaction is expected to occur and at which the soil system will be poised (i.e., at a lower (H^+), a greater (e^-), or 'electron pressure' is needed to effect the given reduction).

Buffering of ion activities via dissolution-precipitation, ion exchange, and ligand complexation

The soil solution activities of ions other than H^+ and OH^- are intensity measurements that may be controlled by dissolution-precipitation, ion exchange, and ligand complexation reactions responsible for buffering in soils. Some processes maintain ion activities in soil solution, for example exchange, and complexation. Other biotic and abiotic processes may increase or decrease, particular ion activities. The disturbance of these equilibria will induce restorative shifts in accordance with the Le Chatelier principle, which states that the balance of products and reactants in a dynamic chemical equilibrium will shift in response to a perturbation to restore the original balance of reactants and products. For example, if sparingly soluble PbCrO_4 (lead chromate) is present in a soil, Pb^{2+} and CrO_4^{2-} concentrations of approximately $5.3 \times 10^{-7} \text{ mol L}^{-1}$ will be maintained in soil solution as controlled by the solubility product, K_{sp} , of 2.8×10^{-13} . Any process that depletes the soluble Pb^{2+} or will induce the dissolution of a small amount of solid PbCrO_4 to restore the equilibrium activities of the Pb^{2+} and CrO_4^{2-} . Similarly, additions of these ions to the soil solution will induce precipitation of more PbCrO_4 . In this way, the ion activities are buffered and maintained in soil solution, as shown in Eq. (5):

Similar reactions occur via cation and anion exchange on charged colloids to buffer ion activities, as discussed above for soil acidity buffering. The suite of exchangeable cations in soils is dominated by Ca^{2+} , Mg^{2+} , K^+ , Na^+ , H^+ , and Al^{3+} , depending on the pH of the soil, the mineralogy of the soil parent material, the aluminosilicate clay mineralogy, plant uptake, microbial processes, and human-induced changes in the soil conditions. Multiple equilibria are established in any soil, but all comprise a capacity factor, represented by the exchangeable cations, and an intensity factor. The capacity factor is sometimes called the 'quantity' term, and the quantity-to-intensity ratio (Q/I) is a measure of the nature of the cation or anion exchange buffering reactions responsible for maintaining ion activities in soil solution. Eq. (6) represents a Ca-K cation exchange reaction for such a Q/I relationship:

in which Ex-Ca represents solid-phase, exchangeable Ca, $\text{K}^+(\text{aq})$ is soluble K^+ , Ex-K₂ is exchangeable K^+ , and $\text{Ca}^{2+}(\text{aq})$ is soluble Ca^{2+} . Any environmental conditions that change the activity ratio of K^+ to Ca^{2+} in soil solution (e.g., changing water content, preferential plant uptake of one cation over the other, precipitation of Ca^{2+} , or addition of Ca- or K-containing materials to the soil) will result in K-for-Ca or Ca-for-K exchange reactions that restore and buffer the ion activities in soil solution. The balance between the ratios of exchangeable Ca-to-K and soluble Ca-to-K in solution can be described by an equilibrium constant, a measure of the buffer capacity between exchangeable and soluble forms of the cations.

The activities of many ions in soil solution are also in equilibrium with complexed or chelated forms of the metals that are also soluble, but in forms in which the positive charge of the cation has been neutralized by negatively charged ligands. Any processes that increase or decrease the activity of the hexaquo form of the 'free' form of the cation, e.g., $\text{Fe}(\text{H}_2\text{O})_6^{3+}$, that is in equilibrium with complexed forms, for example complexed with carboxylic acid groups, hydroxyl ions, or other Lewis bases, will induce a shift in the equilibrium to restore the balance of the complexed and free form of the ion. In this way, the 'free' form of the cation (its activity or intensity) is maintained through equilibrium with the capacity factor, the complexed form. Similar to solubility products and cation

exchange equilibria, a stability constant quantifies the relative thermodynamic stability of the complexed and free forms of a metal in a quantity-intensity relationship.

Summary

To conclude, the capacity of a system to resist changes can be an important property. The pH buffer capacity depends on mineralogy, and the organic and mineral contents, and can be adjusted using amendments such as fresh or pyrolyzed organic matter. Appreciation of the buffer capacity of soils for nutrients leads to reasoned use of fertilizers. The concept of ecosystem buffering, or resilience, underpins strategies to protect ecosystems in the context of climate change and increasing pressures from agriculture and urbanism.

Abstract

The specific surface area (SSA) of soil influences important processes in the subsurface, including the retention of water, the adsorption and release of plant nutrients and contaminants, particle attachment, soil swelling, and soil strength. In this chapter, we present state-of-the-art and novel techniques for direct and indirect determination of SSA together with underlying concepts and theories. Both adsorption-based methods and indirect methods such as proximal soil sensing and empirical modeling are presented. The advantages and limitations of each method are discussed with respect to the intended use of the SSA data.

Key points

- State-of-the-art and novel techniques for the determination of the specific surface area (SSA) of soil are presented.
- The factors affecting the accuracy of each technique are elucidated.
- The underlying concepts and theories for SSA estimation are discussed.

Introduction

The specific surface area (SSA) of soils, expressed as the surface area per unit mass ($\text{m}^2 \text{g}^{-1}$) or per unit volume ($\text{m}^2 \text{m}^{-3}$) of soil, plays a crucial role in numerous processes, including the retention of water, infiltration and drainage, ion exchange, adsorption and release of plant nutrients and contaminants, heat transport and storage, structural soil development, microbial processes, soil swelling, plasticity, cohesion, and soil strength. The SSA may be expressed as total, external or internal SSA. The external SSA comprises the area of the solid-air interface of soil in an oven-dry state, where adsorption of polar or non-polar molecules can occur. On the other hand, the internal SSA consists of the surfaces of interlayers of clays or the micropores of organic material that are inaccessible to gas molecules but are accessible to absorption or uptake of polar molecules (Lu and Zhang, 2020). Consequently, the total SSA of soil is the sum of the internal and external SSA. Different methods interrogate different surface areas as explained in subsequent sections.

For soils, total SSA can range from $<0.1 \text{ m}^2 \text{g}^{-1}$ to $800 \text{ m}^2 \text{g}^{-1}$ depending on the particle size distribution, clay mineral type, and soil organic matter content. Sand-sized particles have small SSA values ($<1 \text{ m}^2 \text{g}^{-1}$), while clay-sized particles have large SSA values (e.g., $800 \text{ m}^2 \text{g}^{-1}$ for pure montmorillonite). Consequently, for most natural soils SSA is primarily governed by the clay size fraction.

Apart from the overall clay content of the soil, the dominant clay mineral strongly influences the magnitude of SSA. For example, kaolinite-rich samples usually have much smaller total SSA than soils containing high surface area clays like montmorillonite, which exhibit very large SSA values when probed with polar molecules such as ethylene glycol monoethyl ether (EGME) which can interrogate internal surface area (Table 1). Soil organic matter reportedly has a large SSA ($560\text{--}800 \text{ m}^2 \text{g}^{-1}$), and for soils that have similar fractions of clay, silt and sand, and identical clay mineralogy, the SSA increases as organic matter content increases when measured using a polar molecule such as water or EGME (Table 1, Fig. 1).

Table 1 Comparison of specific surface area values obtained via N_2 gas adsorption (i.e., external SSA) and ethylene glycol monoethyl ether (EGME) retention (i.e., total SSA) for different soil and clay mineral types.

Fig. 1 Water-sorption derived soil specific surface area for samples with different organic matter contents and clay contents ranging from 4% to 13%. Symbol size is indicative of the clay content.

The SSA of porous media can be estimated using various methods. This may involve direct physical methods such as measurement of the particle size and shape with scanning electron microscopy, X-ray micro-computed tomography to estimate SSA from 3D images of particles, and mercury intrusion porosimetry to infer SSA from the effective pore size distribution (e.g., Borkovec et al., 1993; Maroof et al., 2020). Commonly used methods include adsorption or desorption methods where the deposition or retention of a liquid or vapor from the mineral or organic surface is measured. Liquid phase adsorption involves the use of ethylene glycol, EGME and methylene blue. Gas phase adsorption includes the use of water vapor (H_2O), nitrogen (N_2), or carbon dioxide (CO_2). For small SSA media (e.g., $<1 m^2 g^{-1}$), krypton (Kr) or argon (Ar) gas may be used due to their lower vapor pressure at 77 K. Each method presents unique challenges and, in some cases, measures different surface areas (i.e., total or external). Therefore, it is important to recognize the dependence of SSA data on the measurement method and to select one or more methods that are appropriate for the system of interest.

Methods for determining SSA

Mass-volume estimation methods

Direct physical measurement of SSA typically involves the use of light or [electron microscopy](#) to determine the shape and dimensions of individual soil particles. These observations are supplemented by X-ray diffraction measurements to assess the crystallographic structure and interlayer spacing of clay minerals. Provided that a characteristic particle shape and size can be determined, the SSA can be obtained from mass-volume relationships. For example, the SSA of a spherical particle may be calculated with Eq. (1):

$$SSA = \frac{4\pi r^2}{\rho_s V_s} = \frac{4\pi r^2}{\rho_s \frac{4}{3}\pi r^3} = \frac{3}{\rho_s r} \quad (1)$$

where r is the radius of the solid particle, ρ_s is the density of the solid, and V_s is the volume of the solid. Using this approach, the specific surface area of quartz sand with a particle diameter of 1.0×10^{-3} m and a particle density of 2.65×10^3 kg m⁻³ is 2.26 m² kg⁻¹. In practice, SSA values of sands determined by direct observation are often several orders of magnitude smaller than measured values due to the presence of non-spherical particles, [surface roughness](#), and the presence of fine particles ([Table 1](#)).

An analogous mass-volume approach can be used to estimate the SSA of clay minerals, provided that the structural formula and unit cell dimensions are known. For example, [montmorillonite](#) with a nominal structural formula of $K_{0.66}Si_{8.0}(Al_{3.34}Mg_{0.66})O_{20}(OH)_4$ and unit cell dimensions of $a = 5 \times 10^{-10}$ m, $b = 9 \times 10^{-10}$ m, and $c = 9.5 \times 10^{-10}$ m. Assuming that the particle density is approximately 2.8×10^3 kg m⁻³, and that the edge area (i.e., c -dimension) is negligible compared with the area of the basal surfaces (i.e., a - and b -dimensions), the SSA of the montmorillonite can be estimated as:

$$SSA = \frac{2ab}{\rho_s V_s} = \frac{2(5.0 \bullet 10^{-10} \text{ m})(9.0 \bullet 10^{-10} \text{ m})}{(2.8 \bullet 10^3 \text{ kg m}^{-3})(5.0 \bullet 10^{-10} \text{ m})(9.0 \bullet 10^{-10} \text{ m})(9.5 \bullet 10^{-10} \text{ m})} = 7.52 \bullet 10^5 \text{ m}^2 \text{ kg}^{-1} \quad (2)$$

Using a slight variation of Eq. (2), the SSA of the montmorillonite can also be estimated from the molecular weight of the unit cell and Avogadro's number (N_A):

$$SSA = \frac{(2ab)(N_A)}{MW_{\text{mont}}} = \frac{2(5.0 \bullet 10^{-10} \text{ m})(9.0 \bullet 10^{-10} \text{ m})(6.022 \bullet 10^{23} \text{ mol}^{-1})}{7.447 \bullet 10^{-1} \text{ kg mol}^{-1}} = 7.52 \bullet 10^5 \text{ m}^2 \text{ kg}^{-1} \quad (3)$$

The relationships presented in Eqs. (2) and (3) apply to clay minerals that exist as flat, plate-like structures with a thickness corresponding to that of the unit cell. When water is removed from expandable clay minerals, the interlayers collapse. The resulting clay particle will then consist of several unit cells stacked on top of one another. If the number of unit cells contained in a collapsed montmorillonite particle is 10, the resulting surface area would be approximately 7.5×10^4 m² kg⁻¹.

The mass-volume methods described above are generally limited in applicability to clean sands or pure clay mineral samples. Many soil constituents, including [metal oxides](#) and organic matter, exist as irregular or poorly defined amorphous structures, which are challenging to characterize. Furthermore, the SSA of natural soils cannot be treated as a strictly additive property due to surface coatings and mineral-organic matter associations. Except in a few limited cases (e.g., clean sands), the SSA of a whole soil should not be estimated using a summation procedure based on the surface area contributions of individual soil constituents.

Sorption-based methods for SSA determination

Adsorption from solution

The SSA can be derived from the adsorption of dissolved molecules from solution as long as the resulting adsorption isotherm has a limiting or maximum value. Such adsorption isotherms are classified as Type I and can be described by the Langmuir adsorption model ([Fig. 2](#)). The Langmuir model can be derived by assuming that, once equilibrium is reached, the rate of solute adsorption onto open surface sites is equal to the rate of solute desorption from occupied surface sites. Several assumptions are inherent to the Langmuir model, including: (1) adsorption is localized or site-specific; (2) no interactions occur between adsorbed molecules; (3) the energy of adsorption is constant for all adsorption sites; (4) the adsorption capacity of the solid is limited; and (5) the maximum adsorption capacity corresponds to monolayer coverage. For solid-liquid systems the Langmuir equation may be written as:

$$C_s = \frac{C_{s,\text{max}} \bullet \beta \bullet C_a}{1 + \beta \bullet C_a} \quad (4)$$

where C_s is the solid-phase concentration of solute at equilibrium, $C_{s,\text{max}}$ is the maximum solid-phase concentration, β is the ratio of the adsorption and desorption rates, and C_a is the aqueous-phase concentration. A series of Langmuir isotherms is presented in [Fig. 2](#) to illustrate the effect of increasing the value of β from 0.01 to 0.25 L mg⁻¹ with $C_{s,\text{max}}$ fixed at 1.0 g kg⁻¹. As the value of β increases, the rate at which the adsorption isotherm approaches the maximum sorption capacity of the solid ($C_{s,\text{max}}$) increases. However, the shape or steepness of the isotherm has no bearing on the maximum sorption capacity, which is used to calculate SSA.

In practice, one can obtain the β and C_a parameters by fitting Eq. (4) to measured adsorption data using non-linear regression analysis software. Some organic molecules that are used in combination with the Langmuir model to determine SSA include methylene blue or cationic surfactants such as cetylpyridinium bromide (CBP) ([Greenland and Quirk, 1964](#)). On most mineral

Fig. 2 Effect of changes in β on the Langmuir adsorption isotherms.

surfaces, adsorbed CPB molecules form a double layer, yielding an effective molecular area of $2.7 \times 10^{-17} \text{ m}^2$. However, for expandable clay minerals, the adsorbed CBP bilayer on the interlayer surfaces is shared and yields an effective molecular area of $5.4 \times 10^{-17} \text{ m}^2$. Thus, the external surface area has to be determined separately from the nitrogen sorption isotherm at liquid nitrogen temperatures using the Brunauer-Emmet-Teller equation, the N_2 -BET method, to be able to quantify the contribution of internal surfaces to the overall adsorption of CBP. Furthermore, in samples rich in iron or aluminum oxides, the use of CBP can be challenging, as it may not form complete double layers on such surfaces. Consequently, the sesquioxides present have to be removed before analyses of SSA.

Gas adsorption

The adsorption of gas to determine SSA assumes that one gas molecule covers a defined surface area. When the whole sample surface is covered by one layer of the gas (termed the monolayer capacity) the SSA of the sample can be derived from the monolayer capacity. A gas adsorption isotherm can be obtained by measuring the quantity of gas adsorbed on the sample surface over a range of relative pressures at a constant temperature. Similarly, a desorption isotherm is obtained by measuring the gas remaining on the soil surface when the relative pressure is gradually reduced.

The adsorption isotherms obtained can be combined with an isotherm or physically-based model to quantify SSA. The adsorption process may conform to different isotherm types, depending on the clay mineral type present in the soil. For most cases, solid surface sorption typically exhibits a Type II isotherm (Fig. 3), where molecules are adsorbed in multiple layers.

Fig. 3 Effect of changes in α on the Brunauer-Emmet-Teller (BET) adsorption isotherm when $X_m = 1 \text{ g kg}^{-1}$.

The commonly used isotherm model used for SSA measurement in combination with gas adsorption is the Brunauer-Emmet-Teller (BET) equation. This equation is based on the Langmuir model, modified to account for multilayer formation assumes that physical sorption involves the formation of many molecular layers of adsorbate on the adsorbent surface. The BET equation assumes that (a) the heat of adsorption of the first molecular layer is constant, (b) the heat of adsorption for the second and subsequent layers is constant and equivalent to the heat of condensation, (c) adsorption and desorption occur only from exposed layers, and (d) Langmuir theory assumptions apply to each layer. The equation is parameterized using the measured adsorption data to obtain the monolayer adsorbed gas mass:

$$C_s = \frac{X_m \cdot \alpha \cdot P/P_0}{[(1 - P/P_0)(1 - P/P_0 + \alpha \cdot P/P_0)]} \quad (5)$$

where C_s is the mass quantity of sorbate adsorbed (kg kg^{-1}) at a vapor pressure, X_m is the quantity adsorbed (kg kg^{-1}) when the sorbent is covered with a molecular monolayer and α is a constant related to the heat of adsorption, P/P_0 = relative vapor pressure, where P is the vapor pressure and P_0 is the saturated vapor pressure. The dimensionless α parameter can be mathematically defined as:

$$\alpha = \exp \left[\frac{E_1 - E_L}{RT} \right] \quad (6)$$

where E_1 is the heat of adsorption of the first molecular layer of the sorbate; E_L is the heat of condensation of the sorbate; R is the molar gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$), and T is the absolute temperature (K). The BET equation is identical to the Langmuir equation when the number of adsorbed layers equals one.

A series of BET isotherms is shown in Fig. 3 for α equal to 1, 10, and 100, with X_m fixed at 1 g kg^{-1} and n equal to infinity. As the value of α increases, the inflection point or 'knee' of the BET adsorption isotherm becomes more evident. The inflection in the BET adsorption isotherm corresponds approximately to the point of monolayer coverage. Below the inflection point, gas adsorption occurs on exposed surfaces. The gradual increase in adsorption above the inflection point corresponds to multilayer formation on the surface, while the steep asymptotic rise in adsorption at relative vapor pressures approaching unity ($P/P_0 = 1$) corresponds to liquid condensation.

Commonly used adsorbates for gas sorption in combination with the BET equation include nitrogen (N_2), CO_2 , krypton and argon (for $\text{SSA} < 0.1 \text{ m}^2 \text{ g}^{-1}$), and water vapor. Regardless of the gas or vapor used, the area covered by one molecule on the surface must be known or estimated. For N_2 this is estimated to be $1.62 \times 10^{-19} \text{ m}^2$, and for water it is $10.8 \times 10^{-20} \text{ m}^2$.

The most commonly used gas for determining SSA is N_2 and measurements are conducted at the boiling temperature of liquid nitrogen at atmospheric pressure (-196°C). To obtain the N_2 -adsorption isotherm, the amount of gas adsorbed is computed for each incremental gas dosage based on the change in vapor pressure at equilibrium. Upon reaching the saturated vapor pressure ($P/P_0 = 1$), the process may be reversed (the vapor pressure is incrementally reduced) to obtain a desorption isotherm, from which pore size analysis can be performed. In general, automated surface area instruments report gas adsorption data as the volume of gas adsorbed per gram of soil at standard temperature and pressure (STP). Volumetric gas adsorption data are converted to a mass basis (grams per kilogram) using the molar volume of an ideal gas at STP ($22.414 \text{ L mol}^{-1}$) and the molecular weight of the gas (e.g., $\text{N}_2 = 28.02 \text{ g mol}^{-1}$).

The second experimental approach used to measure gas or vapor adsorption is based on the continuous introduction of a gas stream at constant vapor pressure. Once equilibrium is attained, the soil sample is either weighed or extracted to determine the

Fig. 4 Adsorption and desorption of N_2 on hydrogen peroxide (HP)-treated and untreated Webster soil.

amount of adsorbed gas. The vapor pressure of the gas flow stream is then incrementally increased over the desired vapor pressure range to obtain the adsorption isotherm. Typical nitrogen adsorption and desorption isotherms for two soils are shown in Fig. 4.

To obtain values for the two unknown parameters in the BET equation, C and X_m , Eq. (5) can be fitted directly to the experimental adsorption data using nonlinear regression.

The N_2 -BET SSA is then calculated as:

$$SSA = \frac{X_m \cdot N_A \cdot A_m}{M_w} \quad (7)$$

where N_A is Avogadro's number ($6.02 \times 10^{23} \text{ mol}^{-1}$), A_m is the area covered by one sorbate molecule ($1.62 \times 10^{-19} \text{ m}^2$ for N_2) and M_w is the molecular weight of the sorbate (28.02 g mol^{-1} for N_2). For example, if X_m was determined as 5 g g^{-1} , the N_2 -BET SSA is calculated as:

$$SSA = \frac{0.005 \text{ g g}^{-1} \cdot (6.022 \cdot 10^{23} \text{ mol}^{-1}) \cdot (1.62 \cdot 10^{-19} \text{ m}^2)}{28.02 \text{ g mol}^{-1}} = 17.4 \text{ m}^2 \text{ g}^{-1} \quad (8)$$

Due to the inability of N_2 to penetrate the interlayer spaces of expandable clay minerals, the SSA determined from N_2 -BET is often considered the external surface area.

Treatment and preparation of soil samples before N_2 adsorption can strongly influence the measured SSA (Figs. 4 and 5). For example, the removal of soil organic matter or carbonates often leads to increased SSA values. This has been attributed to the exposure of mineral surfaces covered by organic matter and the separation of mineral particles held together by organic matter bridging. Data from 10 Arizona soil samples confirm that the N_2 -BET SSA of the samples consistently decreased after the removal of organic matter and carbonates (Fig. 5).

As previously mentioned, the surface of the sample must be cleaned to remove other adsorbed gases (e.g., water vapor) before commencing with the measurement of adsorption of the test gas. The cleaning process often involves a combination of outgassing and high temperatures. The drying or dehydration process can lead to unwanted phase changes in iron hydroxides or collapse of the interlayer space of expandable clay minerals, which are then not accessible to inert gases such as N_2 . In addition, [electron microscopy](#) suggests that air-drying of soil samples results in the collapse and shrinkage of soil [humic acid](#), whereas freeze-drying maintains a complex structural network characteristic of soil organic matter. Thus, freeze-drying of soils to remove the water before N_2 -BET analysis tends to result in larger surface area values, which may be more representative of natural conditions. Alternatively, a low outgassing temperature may be considered to reduce the negative effect on gas adsorption.

Water vapor sorption

Water is a polar covalent molecule and it is attracted to the exchangeable cations in clay minerals present in soils. Consequently, water molecules can penetrate the interlayer space of expandable clay minerals, and measurement of the amount of water sorbed at a given relative humidity (RH) provides a measure of the total SSA. Water vapor can be used to determine SSA with two approaches: (a) a single-point measurement that assumes monolayer coverage (X_m) at a specific RH , for example, 0.20 for soil samples with non-swelling clays and 0.47 for samples containing swelling clays ([Newman, 1983](#))—the SSA can then be determined from Eq. (7), and (b) a combination of water vapor sorption isotherms and associated models.

Fig. 5 Comparison of specific surface areas determined with N_2 -BET for ten samples before and after removal of organic matter and calcium carbonates. Partly from Arthur et al. (2013).

Although relatively simple, the single-point measurement approach is strongly affected by the clay minerals present in the sample. Since soil samples are often a mixture of different clay minerals, assuming monolayer coverage using a fixed RH to estimate SSA can lead to errors. The increased availability of instrumentation such as the Aqualab Vapor Sorption Analyzer (METER Group, Inc., Pullman, WA, United States) or Dynamic Vapor Sorption (Surface Measurement Systems, Rosemond Rd., United Kingdom) for rapid measure of water vapor sorption isotherms for clays and soil samples has made the use of the whole isotherm more convenient than in the past. These instruments measure both water vapor adsorption and desorption isotherms within a relatively short time (1–3 days depending on sample composition).

The water vapor sorption isotherms may be parameterized using the BET equation for the RH range between 0.1 and 0.4 since the BET equation does not properly characterize the effect of swelling clay. Consequently, more versatile models have been proposed that can fit the isotherm in the typical RH range from 0.05 to 0.95 (Arthur et al., 2018). Two of these models are the Guggenheim-Anderson-de Boer (GAB) model and the Tuller-Or (TO) model. Examples of water vapor sorption isotherms for three samples and their corresponding TO and GAB model fits to the data are shown in Fig. 6.

The GAB model is similar to the BET equation but has an additional parameter (K) to compensate for the assumption that the sorption state of the water molecules in the layers beyond the first is the same but different from that of the pure liquid state:

$$X = \frac{X_m \cdot C \cdot K \cdot RH}{[(1 - K \cdot RH)(1 - K \cdot RH + C \cdot K \cdot RH)]} \quad (9)$$

where X is the mass quantity of water vapor adsorbed (kg kg^{-1}). When $K = 1$, the GAB model reduces to the BET equation and the X_m and C values will be the same for the two equations. The value of X_m obtained by fitting either the GAB (Eq. (9)) or BET (Eq. (5)) equations to the water sorption isotherm data is then used to determine the SSA using Eq. (9).

The TO model (Tuller and Or, 2005) is a physically based water film sorption model that relates X (kg kg^{-1}) to the matric potential, ψ ($\text{m H}_2\text{O}$) and SSA ($\text{m}^2 \text{kg}^{-1}$) as:

$$X = \sqrt[3]{\frac{A_{svl}}{6 \cdot \pi \cdot \rho_w \cdot g \cdot \psi}} \cdot SA \quad (10)$$

where A_{svl} (J) is the Hamaker constant for solid-vapor interactions through the intervening liquid (-6×10^{-20} J), ρ_w is the density of water (1000 kg m^{-3}) and g is the acceleration due to gravity (9.8 m s^{-2}). Similar to the BET equation, the TO model is parameterized with the water vapor isotherm data using nonlinear regression. The fitting parameter is the SSA which is optimized during the parameterization procedure.

Based on measured data, the water vapor sorption based SSA determined by the GAB model is often slightly higher but correlates well with that obtained by the TO model (Fig. 7).

Fig. 6 (A) Example of measured water vapor sorption isotherms for three samples with different soil specific surface areas (SSAs), (B) fit of Tuller and Or (2005) model to the adsorption isotherms, and (C) fit of the Guggenheim-Anderson-de Boer (GAB) model to the desorption isotherms. The numbers in the legend of panels B and C are the SSA estimates in $\text{m}^2 \text{g}^{-1}$ from the two models (Eqs. (9) and (10)). Adapted from Knadel M, de Jonge LW, Tuller M, Rehman HU, Jensen PW, Moldrup P, Greve MH, Arthur E (2020) Combining visible near-infrared spectroscopy and water vapor sorption for soil specific surface area estimation. *Vadose Zone Journal* 19(1): e20007.

Fig. 7 Comparison of specific surface area ($\text{m}^2 \text{g}^{-1}$) for 48 soil samples determined from the water vapor desorption isotherm combined with the Tuller-Or and GAB models.

Furthermore, the soil water vapor sorption isotherm is hysteretic and thus the SSA derived from water sorption isotherms will depend on whether the adsorption or desorption isotherm is used. It is preferable to use the desorption isotherm to determine SSA because the adsorption isotherm is sensitive to the initial water content, and presence of hydrophobic compounds, and is more affected by intermolecular forces than the desorption isotherm.

Before measurement of the water sorption isotherms, samples can be oven-dried (to avoid the effect of initial water content) or have their organic matter removed to quantify the mineral surface area. These pretreatments affect the final SSA depending on the soil or clay mineral type. For soils that are coarse-textured (sandy soils) and have significant amounts of organic matter content, oven drying can lead to strong hydrophobic effects and a resultant significant decrease in SA. However, oven drying does not seem to affect fine-textured or clay samples.

EGME retention

Similar to water, polar liquids such as EGME or ethylene glycol (EG) can be used to determine SSA. These liquids can also penetrate the interlayer lattice of clay minerals and give an estimate of the total surface area. The method is based on the retention of EG or EGME that forms a monolayer on the surface of the sample, and if the surface area that is occupied by one molecule is known, the SSA can be calculated using Eq. (11). To obtain the monolayer, excess liquid is added to the dry sample, which is allowed to evaporate under vacuum until only one monolayer remains. It is assumed that the monolayer is obtained when the weight of the sample becomes stable after multiple weighing.

Previously, EG was used to determine SA, but the rather long equilibration time between EG and samples has led to a preference for the more volatile EGME.

In practice, an initially air-dried and preferably sieved sample is mixed with laboratory-grade EGME until a slurry is formed. The EGME-sample slurry is subsequently sealed in a desiccator that is connected to a vacuum pump. A solvate of EGME mixed with calcium chloride is placed in the headspace of the desiccator, to maintain a constant EGME vapor pressure and minimize the loss of EGME from the monolayer that forms on the sample surfaces. Vacuum is applied to accelerate the evaporation of excess EGME from the samples. Thereafter, the samples are weighed repeatedly at a resolution of 0.0001 g until a constant mass is obtained. The SSA of the sample is then calculated as follows:

$$\text{SSA} = \frac{W_{\text{EGME}}}{W_{\text{OD}} \bullet CF_{\text{EGME}}} \quad (11)$$

where W_{EGME} is the mass of the EGME retained by the soil at the applied vacuum, W_{OD} is the mass of the oven-dried sample and CF_{EGME} is the mass-surface area conversion factor for EGME ($2.86 \times 10^{-4} \text{ g m}^{-2}$). It is recommended that the SSA of a reference expandable clay mineral, such as Wyoming montmorillonite (SWy-1), be measured to confirm the value of the conversion factor and to ensure that the experimental procedure is operating properly.

Previously, it was considered necessary to remove organic matter from test samples before the determination of EGME SSA to avoid partitioning of EGME into organic matter. Other studies have shown that this may not be necessary as the samples that have the organic matter removed often show similar EGME SSA to those with no pretreatment (Heister, 2014). The exchangeable cations

present in a sample may affect the retention of EGME, through cation solvation that leads to increased SSA. Further, EGME tends to cluster around cation exchange sites before a complete monolayer is formed, and this may lead to erroneous SSA values. Despite these challenges, the EGME method provides a viable alternative for determining the total SSA of most soil and clay samples.

Indirect methods

As described above, the determination of SSA can be a tedious process. Consequently, the SSA may be estimated using indirect methods that involve proximal sensing or the use of empirical models that correlate SSA to easy-to-measure soil properties.

Proximal sensing methods (spectroscopy)

Visible near-infrared (VNIR) spectroscopy (400–2500 nm wavelengths) combined with multivariate data analysis is an indirect method to estimate the SSA of soils. This is possible because light absorption in this region is characteristic of the clay type, clay content and organic matter content of the soil. Since SSA is dependent on these soil properties, the spectra obtained for a given soil can be correlated with its measured SSA. The measurement of a VNIR spectrum is rapid (<2 min per sample). In practice, the approach involves the development of partial least squares (PLS) regression models from VNIR spectra and a reference SSA measured by EGME or water sorption for a group of soils (e.g., Knadel et al., 2020). The developed calibration models are validated with an independent dataset, and the models are afterwards used to estimate SSA for new samples for which VNIR spectra are available. This method is usually applied to air-dry samples since the presence of water interferes with light absorption.

Empirical models or pedotransfer functions

The use of empirical models to estimate SSA is appealing as it is based either on easily measurable soil properties like hygroscopic water content, or readily available soil properties (e.g., clay content, silt content, organic matter content, Atterberg limits). Based on a dataset of 208 soil samples, it is possible to estimate the total SSA measured by EGME from the following empirical model based on clay and organic carbon contents. That had the following variable ranges:

$$\begin{aligned} \text{SSA} &= -1.95 + 2.49 \bullet \text{clay} + 3.16 \bullet \text{OC} \\ N &= 208; R^2 = 0.78; \text{SEE} = 13.8 \end{aligned} \quad (12)$$

where N is the number of samples and SEE is the standard error of the SSA estimate. The data boundaries of the input and predicted variables were clay content [1–56%], organic carbon content [0–8.4%], and SSA [2–161 m² g⁻¹].

Conclusions

Despite the refinement of the methodology for measuring SSA over the years, there can be large differences in the measured SSA depending on the sample characteristics, the sorbate used, and the sample pretreatment. The SSA determined for soil samples, which contain 1:1 layer (i.e., non-expandable) clay minerals, such as kaolinite, and have small contents of organic matter, is often similar regardless of whether the N₂-BET, EGME or water vapor sorption method is used. The EGME and water vapor sorption methods provide reliable estimates of the “total SSA” for most soil and clay samples, but for samples that have large amounts of organic matter, the methods may overestimate the total surface area. This is due to the potential for partitioning or dissolution of the EGME into soil organic matter and the clustering of EGME or water molecules around cation exchange sites. The pretreatment of samples such as drying or removal of organic matter may induce changes in the soil surface structure that will change the available surface area. An optimal approach will be to determine both the “total” and “external” SSA using the EGME or water vapor and the N₂-BET methods, respectively. Based on these two measures, it is possible to quantify the internal surface area and identify sample characteristics or pretreatment effects.

Abstract

In soils with a neutral reaction, the metal cations calcium, magnesium, potassium and sodium are electrostatically attracted to soil particles, described as an electric double layer (EDL) of positively charged cations and negatively charged surfaces. In soils dominated by permanently charged clay minerals, cations in the EDL are rapidly and reversibly exchanged with cations in the bulk solution, as described by selectivity constants. In soils low in clay minerals, the major source of negative charge is soil organic matter and variably charged metal oxides. In acidic organic and forest soils, cation exchange between aluminum and hydrogen ions is an important pH buffering process.

Key points

- Cation exchange is an important chemical reaction in soils that governs the plant availability of nutrients such as calcium, magnesium and potassium.
- The source of negative surface charge in soils is permanently charged clay minerals, variably charged metal oxides and soil organic matter functional groups.
- Different soils may be dominated by different types of cation exchange. Sodium–calcium exchange may be important in high-pH clay soils and aluminum–hydrogen ion exchange in low-pH forest soils.
- Cation exchange can be described quantitatively with reversible, thermodynamic equations. Constants for these equations are conditional because of difficulties in estimating the activity of cations adsorbed by surfaces and occupying the electrical double layer.
- The term ‘base cation’ can easily be misleading for calcium, magnesium, potassium and sodium. In a relatively narrow pH range, the saturation of soil negative charges by these cations (‘base saturation’) is often positively related to pH.
- The pH-dependent chemistry of aluminum hydrolysis and bonding to soil organic matter complicates cation exchange modeling in low-pH soils. This could be overcome by introducing operationally defined exchangeable and non-exchangeable fractions of Al (aluminum) cations.
- In moderately acidic soils, aluminum hydrolysis buffers change in soil pH. In highly acidic soils, exchange between aluminum and hydrogen cations is an important pH buffering process.

Introduction

The study of cation exchange is often credited as the beginning of the discipline of soil chemistry. Early work by H.S. Thompson, followed closely by J.T. Way, was published in 1850 in the Journal of the Royal Agricultural Society of England (Thompson, 1850; Way, 1850). They observed that a cation such as NH_4^+ (ammonium) will displace Ca^{2+} (calcium) from soil and do so rapidly, reversibly and quantitatively. These results still hold essentially true for many soils and combinations of common exchangeable cations, e.g. Na^+ (sodium), K^+ (potassium), NH_4^+ , Mg^{2+} (magnesium), and Ca^{2+} . These cations can be modeled as being held in the

soil by weak, electrostatic interactions with negatively charged surfaces. In this idealized representation, the cations remain hydrated in a diffuse swarm or layer close to the soil surface but do not directly bond. The sum of the negative charges is termed the cation exchange capacity (CEC) of soil. Early work focused on agricultural soils in which the source of the negative charge was largely from clay minerals with isomorphic substitution, e.g. an Al atom with +3 charge substituting in the crystal structure where a Si (silicon) atom with a +4 charge is usually located. This type of charge is termed 'permanent,' because it is independent of pH. Cation exchange processes were relatively straightforward to study in these settings, but are more complex in soils with 'variably' (pH-dependent) charged minerals, such as iron (Fe) oxyhydroxides, and in acidic soils where aluminum is more soluble and reactive. The only finding from Way's early work that has not held up is his assertion that soil organic matter (SOM) had no charge. Subsequent work has shown the importance of SOM, and in fact, it is the primary source of CEC in many soils, especially those with a low clay content. Research on cation exchange processes has continued for the past 170 years with many advances in both our conceptualization and mathematical description of exchange reactions, although much of the focus has remained on clay minerals as the source of negative charge.

The preponderance of cations that are held in an exchangeable form in soils, Ca^{2+} , Mg^{2+} , K^+ , and sometimes NH_4^+ , are important plant nutrients. Their availability for plant uptake is primarily a function of a soil's CEC, although some K^+ and NH_4^+ can be fixed and only slowly released from the interlayers of some 2:1 clay minerals. These cations are relatively small and weakly polarizable (hard) Lewis acids (accept a pair of electrons) and interact electrostatically with negatively charged soil surfaces (similar to hard Lewis bases). Because of its prevalence in most parent material, its divalent charge and its energy of hydration, Ca^{2+} is usually the dominant exchangeable cation in the normal pH range of agricultural soils, e.g. pH 5.5–7.5 (Table 1). The CEC of more acidic soils can be dominated by exchangeable Al^{3+} , whereas more alkaline soils may be sodic and dominated by exchangeable Na^+ . The currently used unit for CEC is centimole of charge per kilogram ($\text{cmol}_c \text{ kg}^{-1}$) and most soils range between 5 and 20 $\text{cmol}_c \text{ kg}^{-1}$. This unit was inherited from the commonly used, and numerically equivalent, pre-SI unit of milliequivalent per 100 g of soil and is likely to be the only instance when one will use the cmol notation. The range of CEC in different soils is quite wide, but higher is not necessarily better (in an agricultural sense) as long as sufficient nutrient cations are retained. Coarse-textured soils, low in clay and SOM, may have very low CEC and not be able to retain sufficient calcium for optimal plant growth. The relative affinity of soil surfaces for Ca^{2+} over Na^+ is of global significance because these two elements have similar abundance in the Earth's crust; most of the Na^+ released from weathering ends up in the oceans while Ca^{2+} is retained in soils.

Sources of charge in soils

Permanent negatively charged mineral surfaces

Early researchers recognized that clay was a source of negative charge in soils, but the structure of clay minerals, a subgroup of phyllosilicates, was not understood until the advent of X-ray diffraction techniques in the 1930s. Based on the work of Linus Pauling and others, the layered structure of some common clay minerals was found to have cations substituted by a different cation of similar size but lower charge. For example, the Si^{4+} cation in a silica sheet could be substituted by Al^{3+} , or an Al^{3+} cation in an aluminum sheet could be substituted by Mg^{2+} or Fe^{2+} . Most clay minerals that develop charge have two silica sheets sandwiching one aluminum sheet (2:1 layer) and this isomorphic substitution results in a net negative layer charge. In some geologically-derived phyllosilicates, such as muscovite, the layer charge is balanced exactly by an interlayer cation, such as K^+ , that is part of the crystal structure, and the overall mineral charge is zero. In many soil-derived clays and weathered inherited phyllosilicates, the layers are no longer held tightly together

Podzols were not well represented in this database (see Table 2).

WRB groups are from WRB (2006). The approximate equivalent in USDA soil taxonomy (approx.. USDA) is also provided. The effective CEC (CEC_e) was calculated from the sum of exchangeable (Exch-) cations and the total CEC (CEC_t) was measured at a reference pH of 7.0 or 8.2. The pH (pH_w) is the pH in water.

and water and associated dissolved ions can enter, e.g. illite, a hydrous mica. The exposed clay surfaces have a negative charge that must be balanced by cations in the soil solution. The geometry, distribution and strength of the negative charge is not sufficient to form inner-sphere bonds (strong ionic or covalent associations excluding water molecules) with the cations and a diffuse swarm of hydrated cations balances the charge. This negative charge is considered permanent because it is usually not affected by soil pH, ionic strength, or the type of exchangeable cations present. This permanence may be somewhat less so in acidic soils that foster the precipitation of positively charged polynuclear Al-hydroxides in the clay interlayers, which block some of the permanent charge. The types of soil clay minerals that display this permanent charge tend to dominate the clay-size soil fraction in soils of the temperate regions, such as Europe (including Russia) and the USA, where most of the initial research on soils was performed.

Variably charged mineral surfaces

There are clay minerals, which are a class of phyllosilicates, and there are clay-sized minerals, which include non-silicates such as Al, Fe and Mn (manganese) (oxy)(hydr)oxides. This may be confusing because, in soil science, the word clay is used for two different purposes—particle size and mineralogy. The non-silicates are much more prevalent in acidic and highly weathered soils, such as found in the tropics. The charge on these oxide surfaces is not derived from structural substitution but, instead, from surface functional groups. These are usually -OH groups that can lose or gain an H^+ (hydrogen) and take on a negative or positive charge. The propensity to dissociate and create a negative charge depends on a number of factors that include the nature of the metal, the structure of the mineral and the ionic strength and pH of the solution. Different ions can also affect the charge, but the ion determining primary electrical potential is H^+ and thus pH is usually the controlling factor. Some of the variably charged minerals can have a net positive charge, especially at low pH, and there is a pH at which the overall net charge is zero. These variably charged minerals were not widely researched until the last part of the 20th century, when there was more focus on acidic subtropical and tropical soils. However, Sante Mattson, working with a variety of soil types in Sweden, clearly showed variable charge in his 1931 paper: 'The laws of soil colloidal behavior: VI. Amphoteric behavior' (Mattson, 1931). Most other work during this decade, and for many to follow, focused on phyllosilicates that have only minor variable charge on the edges of the Al and Si sheets.

Charges of soil organic matter functional groups

The importance of SOM for the CEC of soils, similar to variably charged minerals, was documented in the early part of the 20th century by a few researchers, including Mattson, but its general importance for CEC was only recognized decades later. It is now clear that both clay-size minerals (phyllosilicates and metal oxyhydroxides) and SOM contribute to the negative charge of soils and SOM can be the primary source of charge. This is especially true in many forest soils developed from coarse textured parent material, e.g. glacial drift, where surface horizons can be quite low in clay content but quite high in SOM, and higher CEC is strongly correlated with higher SOM (Fig. 1) (Johnson, 2002). The charge on SOM develops from the dissociation of H^+ from primarily carboxylic groups and to a lesser extent phenolic groups. These functional groups have been found to have a wide range of acid strengths (pKa values, which measure the propensity of an acid to release H^+) so that raising or lowering the pH will usually increase or decrease the negative charge of soil linearly, and buffer its pH value. What is not widely recognized, however, is that the negative charge per amount of SOM does not vary much in field soils below a pH of about 5.5 even though adjusting the pH of an individual soil sample will cause a dramatic change (Ross et al., 2008). This is the result of the interplay between Al, pH, and the development of SOM-associated charge, and will be discussed further below. The SOM does not develop detectable positive charge at any pH. Thus, it is not amphoteric like the metal oxyhydroxides. Adding organic residues, manure or compost to soil can bring about many physical and chemical improvements and is an effective means of increasing a soil's CEC. This can be especially important for sustainable agricultural production on low-clay soils where increased SOM may be needed to maintain soil fertility.

Cation exchange concept and models

Conceptual and mathematical models of cation exchange reactions were developed in the early part of the 20th century with the assumption of an idealized, permanently charged surface. An early approximation, the Helmholtz model, describes the particle–soil solution interface as a charged surface with associated, adsorbed cations. Experimental results were however better described by an exponential decrease in the concentration of cations from the negatively charged particle surface into the bulk solution. This so called diffuse double layer (DDL) is explained by the Guoy–Chapman theory. The DDL, later renamed the electrical double layer (EDL) to be more explanatory, extends out into the soil solution to a distance at which there is no longer any electric force from the surface and the cationic and anionic charges cancel out. Thus, two opposing forces act on ions in the soil particle–bulk solution interface—the electrostatic attraction of cations toward the negatively charged surface (together with repulsion of anions) and diffusion forces by which the excess of cations near the surface migrate along the concentration gradient toward the bulk solution (anions migrate in the opposite direction). The thickness of the EDL can be calculated by the Guoy–Chapman theory, and it varies not only with the magnitude of surface charge but also with the valence and concentration of the ions in the bulk solution. Divalent cations will create a thinner double layer than monovalent cations, as will a larger concentration of ions (a higher ionic strength). The EDL model and associated equations help to explain flocculation and dispersion of charged soil particles as influenced by the relative abundance of cations such as Ca^{2+} (promotes thinner EDL that allows flocculation of soil particles) and Na^+ (promotes thicker EDL that keeps particles dispersed). To improve the fit further to experimental data, several modifications of the

Fig. 1 Relationship between soil organic matter and effective cation exchange capacity (CEC_e) at three different forested watersheds in the northeastern USA (Spodosols and Inceptisols in USDA Taxonomy). Open circles are O horizons and '+' are mineral horizons. Organic matter was measured in the top panel by loss-on-ignition and a direct measurement of carbon ($\sim 58\%$ of SOM) was used in the bottom two panels. The effective CEC (CEC_e) was determined by the sum of exchangeable cations. The source is Johnson CE (2002) Cation exchange properties of acid forest soils of the Northeastern USA. *European Journal of Soil Science* 53: 271–282, part of Fig. 2, which is reproduced with permission.

Guoy–Chapman theory have been proposed. The Stern modification adds a layer of strongly adsorbed cations, also referred to as the Helmholtz layer that effectively decreases surface charge and thus the EDL thickness. In the ideal case, cations adsorbed in the Stern layer are imagined as inner-sphere bonded (non-hydrated), whereas the cations in the EDL are considered fully hydrated (Fig. 2). The propensity of a cation to be adsorbed is a function not only of charge but also the energy of hydration, i.e. the energy released when the cation reacts with water; this reflects the strength of the bond between the cation and the first shell of water molecules. A cation from the same group in the periodic table, e.g. the alkali metals or the alkaline-earth metals, will be preferentially adsorbed in its non-hydrated state if its atomic number and ionic radius are higher and therefore its energy of hydration is lower. Thus K^+ , atomic number 19, will be adsorbed more strongly than Na^+ , atomic number 11, and Ca^{2+} , atomic number 20, will be more strongly adsorbed than Mg^{2+} , atomic number 12. This is the basis for cation selectivity, discussed further in the next section. The theory and equations used to describe the EDL were initially based on the premise of permanently charged surfaces of clay minerals, but have since been adapted for variably charged minerals and functional groups of SOM to cover cation exchange and surface complexation reactions of metals and their ions in soils (Goldberg, 1992; McBride, 1994; Sparks, 1995; Tipping, 2002; Evangelou and Phillips, 2005; Essington, 2015; Strawn et al., 2015).

Cation exchange equations

A variety of equations have been developed to describe exchange reactions between cations in the bulk solution and cations in the so called exchange phase (weakly adsorbed at the surface or in the EDL) of soils. In its simplest form, reactions are restricted to exchange between two cations of the same charge (homovalent, e.g. Na^+ and K^+) or different charge (heterovalent, e.g. Ca^{2+} and K^+) taking place on permanently charged clay mineral surfaces. These reactions take the form of simple chemical equilibria equations, but differ primarily in how the exchange phase is expressed. The difficulty in developing true equilibrium constants, i.e. thermodynamic stability constants, is primarily because of uncertainty in how to calculate the activity of the cations (in principal their effective concentrations) at the surface and in the EDL. It is also difficult to account for electrostatic effects at the surface, i.e. the work required to migrate cations from the EDL into the bulk solution. No suitable method is known. When applied to soils, the heterogeneity of permanent and variably charged surfaces also limits transferability of equilibrium constants. Because the constant in a cation exchange equation incorporates all these factors and uncertainties it is termed a selectivity coefficient and is referred to as conditional rather than being constant. In systems with variably charged particles it also depends strongly on pH and ionic strength. Nonetheless, these equations have been useful in applications such as the soil fertility of the common nutrient cations, effects of

Fig. 2 Conceptual description of the particle surface–soil solution interface of a theoretical soil composed of negatively, permanently charged clay and variably charged natural organic matter (NOM) functional groups and metal oxide surfaces. Anions in solution are for simplicity represented by chloride. The electrical double layer (EDL) has a thickness on the nanometer scale depending on pH and ionic strength. The effective cation exchange capacity (CEC_e) is composed of cations held in the EDL: mono- and di-valent base cations (at pH 7.0, left), and H^+ , $Al(OH)_n^{3-n}$ and BC (at pH 4.5–5.0, right). The total CEC (CEC_t) in addition includes non-exchangeable $RCOOH$ functional groups (H_t-H_e) with a pK_a value of a reference pH (7.0 or 8.2) and below, as well as chemisorbed Ca and Al cations.

liming and in predicting the effect of Na^+ in irrigation water on soil dispersion. Two of the most commonly used equations are presented below and the reader is referred to soil chemistry text books such as [Essington \(2015\)](#) for additional permutations and discussion. Some of the more recently developed equations have a stronger footing in thermodynamics but do not necessarily provide better results.

The Vanselow equation expresses the exchange phase cations as the mole fraction of the total CEC. For a homovalent exchange reaction, this is the same as moles of charge, but this is not the case for heterovalent exchange. In the equation below, the mole fraction of Na^+ , N_{Na^+} , is the moles of Na^+ in the exchange phase divided by the sum of the exchange phase moles of $Ca^{2+} + Na^+$.

Vanselow

$$K_V = N_{Ca}(Na^+)^2 / N_{Na^+}^2 (Ca^{2+}),$$

where K_V is the Vanselow constant, N is the mole fraction in the exchange phase and $()$ is the solution activity.

Gapon

$$K_g = [Ca_{1/2X}] [Na^+] / [NaX] [Ca^{2+}]^{1/2},$$

where K_g is the Gapon constant, X is the exchange phase and the solution cations are expressed as concentrations $[]$.

The Gapon equation expresses the exchange phase in moles of charge instead of a simple mole fraction and uses molar concentration instead of activity in the solution phase. It is probably evident that these two equations will provide different results, but they do not differ dramatically over the normal range of CEC and exchangeable cation concentrations.

What becomes clear when applying these equations is that there is a strong selectivity for different cations, even those of the same valence. For example, at equal concentrations of Ca^{2+} and Na^+ in solution, the equilibrated exchange phase would be over 95% Ca^{2+} . The constant for Ca^{2+}/K^+ exchange tends to be a factor of 10 different from that for Ca^{2+}/Na^+ , and the exchange phase for K^+ is commonly much higher than that of Na^+ . The relative selectivity for common exchangeable cations, also known as the lyotropic series, is $Al^{3+} > Ca^{2+} > Mg^{2+} > K^+ \approx NH_4^+ > Na^+$. The effect of valence is much stronger than that of different hydration energies within a valence, but the latter is also important. Additional cations could be added to this list but these six dominate the exchange phase across a range of soil types and pH. Many other divalent cations found in soils are transition metals, such as Cu^{2+} (copper), Zn^{2+} (zinc), Cd^{2+} (cadmium) and Pb^{2+} (lead), and their interaction with soil surfaces is usually more complex (due to inner-sphere and hydrolysis reactions) than the outer-sphere hydrated ionic behavior assumed for exchange reactions. This complexity is also true for the behavior of Al^{3+} in soils, discussed further below.

Extension of the cation exchange concept to variably charged soils

When the cation exchange concept, originally developed for reactions taking place at the surfaces of permanently charged clays in agricultural soils, was applied to a wider range of soils cations other than Na, K, Mg and Ca had to be considered. In acidic forest soils (e.g. Alfisols, Inceptisols, Spodosols) and highly weathered soils (Oxisols and Ultisols) dominated by variably charged metal oxide minerals and functional groups of SOM, the ‘major cations’ taking part in cation exchange reactions at surface charges of soil components would include H^+ and Al cations (Al^{3+} and its hydrolysis products, collectively written $Al(OH)_n^{(3-n)+}$; $n = 0-3$). During the “acid rain research era” (roughly 1970s to 1990s) simplified models were developed in which the cation exchange between Al^{3+} and the so called base cations (BC: Na^+ , K^+ , Ca^{2+} , Mg^{2+}) was linked to the pH-dependent solubility of the $Al(OH)_3(s)$ mineral gibbsite. This process was described as a major pH buffering mechanism by which soils neutralized H^+ in acid rain and indirectly controlled the nutrient availability and acidity in runoff from soils to surface waters (Christophersen et al., 1982 [ILWAS model]; Cosby et al., 1985 [MAGIC model]; Reuss, 1983). This type of model fits data from B horizons of Spodosols affected by acid rain and with a pH exceeding approximately 4.0–4.5 (Fig. 3), but fails at lower pH as discussed below.

Somewhat earlier, research on clay mineral chemistry conducted at pH values well below neutrality had revealed that the hydrolysis of Al and its products (the cations $Al(OH)_n^{(3-n)+}$) also played a previously overlooked role at permanently charged surfaces (Harwood and Coleman, 1954; Low, 1955). Hydroxy-interlayered vermiculite (HIV) and smectite (HIS) minerals denote permanently charged minerals with part of their negative charge ‘blocked’ by $Al(OH)_n^{(3-n)+}$ cations and/or layers of positively charged polynuclear $Al_x(OH)_n^{(3x-n)+}$ polymers. This effect is largest at pH values in the approximate range of 4.5–6.0 (cf. Fig. 2). When pH is raised further, the hydrolysis of Al and nucleation of non-charged Al-oxyhydroxide minerals, e.g. gibbsite $Al(OH)_3(s)$, reaches completion and covers the interlayers of these minerals, with the permanent negative charge of the clay restored (Bertsch and Bloom, 1996). Similar to Al cations blocking interlayers of HIV and HIS, $Al(OH)_n^{(3-n)+}$ cations may form thermodynamically very stable complexes with functional groups of SOM, e.g. di/tri carboxyls, phenol and quinone (McColl and Pohlman, 1986). These strongly bonded Al cations are not considered readily exchangeable against other cations. When the cation exchange concept was extended to variably charged minerals and soils dominated by such minerals, the CEC concept therefore required some redefinition and extension.

Exchangeable and non-exchangeable aluminum and hydrogen ions

One important extension of the cation exchange concept for variably charged soils is the division of Al into exchangeable and non-exchangeable forms. Aluminum chemistry is markedly different from that of the other major metal cations in soils, which are alkali and alkali-earth metals. It is a primary component of most clay minerals and one of the major elements in the Earth’s crust (third most abundant after oxygen and silicon) but is relatively insoluble at a pH above about 5.5 – 6.0. Below this pH, Al can be solubilized but is also quite reactive and will readily form strong complexes with oxygen-containing functional groups of SOM and oxygen-containing anions such as sulfate and phosphate, and will also hydrolyze to form soluble and insoluble Al-hydroxy polymers. Even though Al participates in numerous reactions in soils, an exchangeable fraction may be operationally defined. A selection of neutral salts of cations that are non-specifically adsorbed to soil particles (e.g. KCl, NH_4Cl , $BaCl_2$) will extract a similar amount of Al from a soil, and this is operationally defined as exchangeable Al. Repeated extractions or leaching with a neutral salt,

Fig. 3 Relationship between Ca saturation of CEC_e and pH (measured in 0.002 M $CaCl_2$) in mineral horizons of Spodosols. A model based on cation exchange between Al and Ca, depicted by the Gapon equation, linked to pH dependent solubility of gibbsite, $Al(OH)_3(s)$, fits observations in B horizon samples (black squares and black curve). In the E horizon samples (open symbols), the model cannot explain the observations. This is because when pH drops below 4.0 (corresponding to ~ 4.5 at pH in water), Al exchanges with H rather than with Ca (or other BCs), and the model collapses. Printed with permission from Reuss JO, Hopper RWE, Walthall PM, and Roswall EC (1990) Aluminum solubility, calcium-aluminum exchange, and pH in acid forest soils. *Soil Science Society of America Journal* 54: 374–380.

or the use of stronger extractants (i.e. more acidic and/or containing polyvalent metal cations competing with Al for oxygen groups or ligands complexing with Al cations) will however extract more Al. This suggests that there is a continuum of strengths of adsorbed Al in soils, but with a neutral-salt-defined fraction assumed to participate in exchange reactions similar to other exchangeable cations. Notably, this fraction will be strongly pH dependent.

Non-exchangeable Al is represented by Al cations (Al^{3+} and partly hydrolyzed forms collectively captured by the formula $\text{Al}(\text{OH})_n^{(3-n)+}$) strongly complexed by SOM functional groups, as well as $\text{Al}(\text{OH})_n^{(3-n)+}$ cations and/or layers of positively charged $\text{Al}_x(\text{OH})_n^{(3x-n)+}$ polymers captured in interlayers of permanently charged minerals and amorphous Al-oxyhydroxide minerals. Notably, this non-exchangeable fraction is still a minor fraction of the total quantity of Al in soils, dominated by aluminosilicate minerals which can only be extracted by total digestion in very strong acid (e.g. concentrated HF, hydrofluoric acid). In forest surface soils with a naturally low pH (<5.0), conditions at which permanently charged clay minerals are not stable, 0.5 M CuCl_2 (copper chloride) has been successfully used as a quantitative extractant of organically adsorbed Al (Juo and Kamprath, 1979), and the difference between 0.5 M CuCl_2 and 1.0 M KCl extractable Al has been used as a measure of non-exchangeable forms of Al in these types of soil (Skylberg, 1999).

Most productive agricultural soils, including those studied in the first century of soil chemistry research, have a pH above 5.5 and no or very little exchangeable Al^{3+} . More acidic agricultural soils of the tropics and subtropics can have sufficient exchangeable Al^{3+} to cause toxicity to sensitive crops. Because of the hydrolysis reactions of Al (transformation of Al^{3+} to $\text{Al}(\text{OH})_n^{(3-n)+}$ cations and H^+) over the pH range of about 4.2 to 5.5 (even higher pH if complexed by SOM, which suppresses hydrolysis), Al has been considered to be an acid cation. With decreased pH below 5.5, exchangeable Al^{3+} should increase in concentration and become a higher percentage of the CEC, but at pH 4.2 and lower, Al hydrolysis is minimal. In this relatively narrow pH range (4.2–5.5), the Al^{3+} fraction of the CEC can be a good predictor of soil pH (negative correlation).

Similar to Al, hydrogen ions become important in the exchange processes of more acidic soils. This is particularly true when pH decreases below 4.2 and $\text{Al}(\text{OH})_3(\text{s})$ is not a stable mineral. At such a low pH, H^+ is a major cation in soil solutions, readily taking part in cation-exchange reactions. Highly acidic Oa horizons can have exchangeable H^+ greater than $10 \text{ cmol}_c \text{ kg}^{-1}$, occupying over a third of the exchange sites (Table 2). In many forest soils with a natural pH below 4.5 in the organic surface horizons and A/E horizons, cation exchange between H^+ and Al^{3+} is the major pH buffering process (Skylberg, 1999; Ross et al., 2008) and H^+ and Al^{3+} dominate the CEC over Na^+ , K^+ , Mg^{2+} and Ca^{2+} (Figs. 4 and 5).

A non-exchangeable pool of H can also be defined, similar to Al. It is composed of H^+ that is not dissociated from SOM functional groups at the pH of the soil or extraction solution (i.e. these functional groups have a pK_a value well above the pH of the soil, Fig. 2). In SOM-dominated soils, e.g. Oa (H) horizons and Histosols, the pool of non-exchangeable H^+ is large, as represented by the protonated carboxyl and phenol functional groups of SOM. This pool is denoted H_t , an abbreviation for total or titratable H^+ . The latter is understood to be non-exchangeable H^+ released from soil by the reaction with OH^- under formation of water during base titration.

Base saturation and CEC definitions

There are two important CEC definitions: the total (CEC_t) and the effective (CEC_e). Total CEC represents all potential negative charges on soil particles when the soil is raised to a reference pH of 7.0 or 8.2 (the latter often used because it is the pH reached in equilibrium with calcite) and is determined as the sum of total H^+ (H_t), total charges of $\text{Al}(\text{OH})_n^{3-n}$ (Al_t) and the sum of charges of the BC. The effective CEC is the sum of neutral salt (1.0 M KCl or equivalent) extractable charges pertaining to H, Al and BC. The sum of these neutral salt extractable cations is intended to represent the negative charge of soil at ambient conditions. Alternative methods for the determination of a soil's ambient CEC have also been developed, where pH and ionic strength are kept buffered at the ambient conditions during the extraction (Gillman and Sumpter, 1986).

The term base cation does not mean the cations Na^+ , K^+ , Mg^{2+} and Ca^{2+} are bases. The term originates from describing soil components as fully hydrolyzed metal oxides, where Na_2O , K_2O , MgO and CaO are indeed bases giving a pH > 10 in reaction with water, while Al_2O_3 and Fe_2O_3 are considered acidic oxides. The BCs are in fact hard Lewis acids that preferentially adsorb to hard

Table 2 The mean effective CEC (CEC_e), major exchangeable cations, organic carbon, and pH from acidic podzols in the northeastern USA.

Soil horizons	n	CEC_e	Exch- Ca^{2+}	Exch- Al^{3+}	Exch- H^+	Org-C	pH_w
		cmol_c/kg				g/kg	
Oa (H)	142	32.3	9.14	7.77	11.92	46.9	3.55
B	26	9.9	0.37	7.72	1.50	8.2	3.96
Oa and A	48	16.4	4.74	7.99	4.71	35.0	3.74

The CEC_e was calculated by the sum of exchangeable cations for the 142 Oa and 26 B horizons, and by the compulsive exchange method of Gillman and Sumpter (1986) for the 48 Oa and A horizons. The CEC_t was not measured for these soils but would include H_t (titratable acidity) and some non-exchangeable Al (Al_t). The pH (pH_w) is the soil pH measured in water. Data are from two sampling campaigns of regional forest soils described in Ross DS, David MB, Lawrence GB, and Bartlett RJ (1996) Exchangeable hydrogen explains the pH of Spodosol Oa horizons. *Soil Science Society of America Journal* 60: 1926–1932, used with permission.

Fig. 4 The positive relationship between total adsorbed $\log (\text{Al}/\text{H}^+)$ on the x-axis and neutral salt (1.0 M KCl) exchangeable $\log (\text{Al}/3\text{H}^+)$ on the y-axis demonstrates that total adsorbed Al (defined by 0.5 M CuCl_2 extraction) and H titrated to pH 7.0 dictates the ratio of Al and H in solution. In the absence of permanent clay minerals and metal oxides (pH is lower than 4.0 in all soil samples where these minerals are not stable), Al^{3+} versus H^+ exchange by soil organic matter functional groups is the process behind the relationship. The 18 soil samples shown in the plot represent 1-cm layers of O and E horizons of two Spodosols. The numbers 1–5 represent 1-cm layers of the E horizon with the zero level set at the interface between O and E. The figure is from Skjellberg U (1999) pH and solubility of aluminium in acidic forest soils: A consequence of reactions between organic acidity and aluminium alkalinity. *European Journal of Soil Science* 50(1): 95–106 and is reproduced with permission.

Lewis bases (i.e. oxygen atoms of minerals or SOM functional groups). While Al^{3+} readily hydrolyzes in most soils, and thus releases 3 H^+ under the formation of $\text{Al}(\text{OH})_3$, the cations Na^+ , K^+ , Mg^{2+} and Ca^{2+} do not hydrolyze below pH values of 10.

The base saturation (BS) is the fraction of CEC accounted for by base cations: BC/CEC_e and BC/CEC_t .

Because of the differences in hydrolysis of BC and Al, the relationship between pH and BS (i.e. BC/CEC_e and BC/CEC_t) in a population of soil samples would be expected to be positively correlated if pH exceeds approximately 4.5 (cf. Fig. 3). Such a positive relationship is a prerequisite for the models developed during the acid rain era (e.g. Christophersen et al., 1982; Reuss, 1983; Cosby et al., 1985) to succeed as pH buffering models in soils.

A related concept is the ideal basic cation saturation ratio (BCSR). Many soil tests will report the saturation of the individual 'base' cations in relation to CEC_t . One can easily find recommendations in the popular literature for attaining ideal saturation ratios of Ca^{2+} charges at 65% (i.e. $\text{exch-Ca}^{2+}/\text{CEC}_t \times 100$), Mg^{2+} at 10% and K^+ at 5%. These ratios are not only proposed to provide proper chemical fertility but also to achieve maximum physical and biological fertility. These ratios are, again, based on historical research that has not withstood the test of time and they may be quite expensive for the agricultural producer to maintain (Kopittke and Menzies, 2007). While it is clear that there can be an imbalance in these exchangeable nutrient cations, numerous studies have shown that the ranges of the BC saturation ratios needed to achieve optimal plant growth are quite wide and encompass those usually found in agricultural soils. Some soils are naturally high or low in Mg, inherited from parent material, and adjusting the Mg^{2+} saturation of CEC_t to 10% could be difficult, expensive and unnecessary. Only excessive additions of one of these BCs can actually cause problems.

Cation exchange in acidic forest soils

In most soils pH is buffered and kept well above pH 4.5 because of kinetically driven weathering (solubilization) reactions with an abundance of aluminosilicate minerals. Exceptions are in the case of inputs of extreme mineral acidity, such as acid mine drainage, or in organic soil horizons such as the Oe (F) and Oa (H) that lack weatherable minerals. It can also be the case in some mineral E and B horizons in forest soils where the abundance, as well as the slow kinetics of aluminosilicate dissolution, is not enough to overcome the instant pH buffering by acidic organic functional groups (carboxylic acids) associated with SOM, contributed by the deposition and turnover of plant litter. In these soils the pH is well below the range for hydrolysis of Al, and the Al^{3+} cation cannot be considered acidic. Under these conditions BS is not positively related to pH (Fig. 5C). It is not difficult to find parallel increases by depth in both pH and exchangeable Al^{3+} . The reason is that H^+ and Al^{3+} ions dominate CEC_e and CEC_t , and the major cation exchange process in these soils is H^+ versus Al^{3+} . At low pH, the minor contribution from BCs and the sites they are associated with, seldom play any role in pH buffering. This is clearly shown by plots of BC, Al_e and H_e vs CEC_e where BC simply increases with increased CEC_e (as controlled by the quantity of SOM) while Al_e increases at the expense of H_e , indicative of $\text{H}^+ - \text{Al}^{3+}$ exchange (c.f. Skjellberg, 1999).

Reuss et al. (1990) demonstrated with a simple model that exchange between Ca and Al is the dominant cation exchange process in the B horizons of acid forest soil with a pH above 4.5–5.0. As expected, in these soils pH is positively correlated to BS when Al–Ca exchange is the dominant cation exchange reaction (Fig. 3). However, in E horizons, where the pH value falls below 4.5, the model applied by Reuss clearly fails, and BS is negatively correlated to pH. This observation was not explained at the time but was later shown to be due to H–Al exchange being the dominant cation exchange process in the O and E horizons of Spodosols

Fig. 5 (A) Relationship between pH and CEC_e in five high-SOM forest soil samples in which pH was adjusted in the laboratory in six different subsamples. (B) Relationship between pH and CEC_e in 105 forest soil samples in which the pH was not adjusted in the laboratory. (C) Change in Al³⁺ saturation of the CEC_e with increasing depth and pH in an idealized Spodosol forest soil profile. Lower Al saturation at lower pH coincides with a higher quantity of SOM. Notably the increase in pH with depth from Oa into Bhs is due to Al—H exchange and the rise in pH above 4.5 is due to Ca—Al exchange. The figures are from Ross DS, Matschonat G, and Skjellberg U (2008) Cation exchange in forest soils: The need for a new perspective. *European Journal of Soil Science* 59(6): 1141–1159, <https://doi.org/10.1111/j.1365-2389.2008.01069.x> and are reproduced with permission.

(e.g. Skjellberg, 1999; Ross et al., 2008). This interpretation was supported experimentally by the work of Hargrove and Thomas (1984) and Walker et al. (1990) on H—Al exchange in acid-washed peats. In Fig. 4, H—Al exchange at SOM sites, with a stoichiometry of 2.47, is the dominant cation exchange process in O and E horizons of two Spodosols. Deviation from the expected value of 3.0 (three H⁺ in exchange for one Al³⁺) is a common observation in studies of Al—H exchange (Hargrove and Thomas, 1984; Walker et al., 1990) and can be explained either by some organically complexed Al retaining a positive charge (R—Al⁺) and/or by electrostatic effects in the EDL, not accounted for in the model. Regardless, it is clear that exchange processes in highly acidic forest soils are better modeled by Al³⁺—H⁺ exchange rather than by exchange involving BC.

At such a low pH of 3.0, the soil solution activity of H⁺ is 1 mmol L⁻¹ which is likely to be higher than any other aqueous phase cation. This H⁺ can be considered exchangeable and, in fact, measurements of CEC in these soils relate better to the sum of exchangeable cations if an estimate of exchangeable H⁺ is included. The source of charge, however, is the dissociation of H⁺ from

organic functional groups and this confounds the view of being truly exchangeable. Nonetheless, due to dissociated acid organic functional groups these organic horizons in forest soils can have quite a large CEC_e (c.f. Table 2) even though BC may not buffer pH. Thus, the CEC_e is also critical for retaining and recycling Ca, Mg and K in these naturally acidic ecosystems.

One other interesting aspect of acidic forest soils is that, unless strongly affected by mineral acidity, the CEC_e per kg of carbon does not appear to vary greatly with pH (Ross et al., 2008). While adjusting pH in the laboratory will cause significant changes in CEC_e , a collection of samples from the field will not usually show an effect of pH below about pH 5 (Fig. 5B). This is, again, related to Al chemistry and pH buffering as discussed above. Highly acidic organic surface horizons will necessarily have lower $\text{Al}_{t,e}$ and thus higher $\text{H}_{e,t}$ because Al is minerogenic and is not recycled by litter to any great extent. Here H^+ will accumulate as a consequence of plant BC uptake and exchange for H^+ . At greater depth in the soil profile the availability of minerogenic Al increases. This will make Al available for reactions. Exchange of H for Al results in an increase in pH but not necessarily in an increase in CEC_e , because most Al bonded to SOM in these horizons is non-exchangeable ($\text{Al}_t > \text{Al}_e$). Deeper into the mineral soil horizons of acid forest soils pH will generally increase because H^+ is consumed by weathering reactions. This results in an increase in BS (Fig. 5B and C) and Al—BC exchange is the dominant cation exchange reaction (Figs. 3 and 5B). Soils receiving large inputs of H^+ may also be depleted of Al at depth in mineral soils, as revealed in some heavily acidified Dutch soils during the acid rain era (Mulder and Stein, 1994). Large inputs of mineral acidity, concentrated by stemflow, were also found to acidify forest soils rapidly in southern Sweden, lowering the CEC_e (Matschonat and Falkengren-Grerup, 2000). Apart from these highly impacted areas, it is difficult to find an effect of pH on CEC in acid forest soils because of the interplay between Al and H.

Cation exchange in highly weathered tropical soils

Soils in the tropics are diverse, possibly more so than at higher latitudes, reflecting a broad range in parent material, climate and age. While many tropical soils contain 2:1 layered clay minerals and permanent CEC, highly weathered soils may develop in humid, older landscapes. In these soils, Oxisols in USDA Taxonomy and primarily Ferralsols in WRB groups (Table 1), the loss of Si from weathering results in the clay size fraction being dominated by 1:1 clay minerals (usually kaolinite) and enriched in Al oxides (primarily gibbsite) and Fe oxides and hydroxides (e.g. goethite and hematite). These minerals have been termed 'low-activity' clays because of the virtual lack of permanent charge (Uehara and Gillman, 1981). This process of desilication (leaching of silicic acid: H_4SiO_4) was historically termed 'laterization' with resulting 'lateritic' soils low in CEC_t ($< 10 \text{ cmol}_c \text{ kg}^{-1}$), low in nutrient cations, high in exchangeable Al, and with a relatively low pH (< 5) (Pincus et al., 2017). The most weathered of these soils may be depleted of 2:1 clays, but any small remnant could contribute disproportionately to the CEC (Nakao et al., 2017).

The 'low activity' mineral fraction means that much of the CEC in the surface horizons can be derived from SOM, accumulated through litter and root turnover or through added amendments. The charge on SOM varies with pH, but always results in a negative charge within the normal pH range of these soils. Subsurface horizons, lower in SOM, may have quite a low CEC_e ($< 2 \text{ cmol}_c \text{ kg}^{-1}$). The pH-dependent variably charged minerals are amphoteric, as discussed above, and Oxisols can therefore develop substantial anion exchange capacity (AEC). The various metal oxides (Mn and Ti (titanium), in addition to the dominant Al and Fe) have a wide range in the pH of their zero point of charge (ZPC). The definitions of ZPC, and the methods for measuring it, have evolved over time and a recent soil chemistry text such as Essington (2015) or Strawn et al. (2015) should be consulted for in depth discussion. The overall net charge of these highly weathered soils evolves toward zero through loss of silica and permanent charge (Chadwick and Chorover, 2001) with SOM being the primary determinant of negative charge by coating the low activity Fe and Al oxyhydroxides minerals (Chorover et al., 2004).

Oxisols (Ferralsols) generally have low native fertility and may be difficult to manage partly because of their low CEC and pH, and therefore have low ability to retain nutrient cations. They occur worldwide throughout the tropics, but are most prevalent in South America and central Africa (Buol and Eswaran, 1999). The dominance of variable charge and the native acidity of these soils results in a wide divergence between the CEC_e and CEC_t . For example, the 225 Ferrasol samples in Table 1 had an average CEC_e of $2.7 \text{ cmol}_c \text{ kg}^{-1}$ and CEC_t of $9.2 \text{ cmol}_c \text{ kg}^{-1}$. Thus additions of lime or other materials to raise the soil pH can increase the retention of nutrient cations by increasing the CEC. However, this may create other soil physical and chemical problems related to flocculation or dispersion and anion (e.g. phosphate) retention due to changes in AEC.

Summary and outlook

Cation exchange reactions are long-studied, fundamental soil chemical processes. In near-neutral soils dominated by clay minerals with permanent negative charge, cation exchange between Ca, Mg, K and Na can be described by relatively simple stoichiometric equations. Cation exchange in soils with variably charged minerals and soil organic matter is more complicated, but can still be modeled by incorporating the effects of pH and ionic strength on surface charge. In acidic soils, H ions and Al cations become important in cation exchange reactions. In forest soils with a pH below 4.5, cation exchange concepts developed for less-acid soils, such as a positive relationship between pH and base saturation, do not apply. In these soils, reactions involving the operationally defined fractions of exchangeable and non-exchangeable H and Al can explain pH buffering through Al—H exchange. Development of geochemical models applicable across the full range of soils found worldwide, and in which all the major ion exchange and pH buffering processes are captured and integrated, remains a challenge in the field of soil science.

Abstract

Soil testing is an important diagnostic tool for determining crop nutrient needs and as part of complex tools to assess the risk of loss from fields. This chapter focuses on nitrogen and phosphorus, for which excess loss from fields impairs surface waters. Concepts discussed include taking representative soil samples, using an appropriate sampling depth, using proper calibration with crop yield response to provide a meaning for test values to determine nutrient application rates for crops, and the role of soil testing in tools to assess the risk of nutrient loss from fields to water resources and water quality impairment.

Key points

- Soil testing is an important diagnostic tool for determining crop nutrient needs and as part of complex tools to assess the risk of loss from fields.
- Taking representative soil samples from the area sampled and using both recommended and consistent sampling depth are very important to assure proper interpretation of soil-test results.
- This chapter focuses mainly on testing soils for the plant macronutrients nitrogen and phosphorus, for which excessive losses from agricultural fields are common and impair surface waters or groundwater worldwide.
- Following recommended laboratory assurance and quality by all laboratories to improve accuracy and minimize bias among laboratories is essential for developing reliable soil testing programs.
- Proper calibration of the soil tests with crop yield response is essential to provide a meaning for test values to determine nutrient application rates.
- Calibration of soil tests also is essential when they are used by themselves or as part of complex tools to predict nutrient loss from fields and water quality impairment.

Introduction

Soil testing is and has been for many decades an important diagnostic tool for determining the nutrient needs of plants and for assessments of nutrients in the environment. Some soils are inherently deficient in plant nutrients whereas other soils originally had sufficient concentrations of nutrients in the past, but reserves have been depleted by crop harvest removal. On the other hand, fertilizer or animal manure applications of some nutrients to initially deficient soils over many years have increased topsoil concentrations to optimum or higher than optimum levels for crops. Thus, soil testing is widely accepted and used in most advanced crop production areas of the world to determine fertilizer needs for crops.

Soil testing also can be used to assess excess accumulation in the soil of harmful elements. Materials such as animal manures and industry by-products may provide various plant nutrients. However, large application rates to soils designed to dispose of the material at a low cost may result in nutrient or element (such as heavy metals) loads that are harmful to plant, animal, or human health. Nutrient management regulations are continuously being modified or developed to address land applications of waste materials. Soil testing is required in many regulations and management guidelines to assess environmentally harmful concentrations of certain elements and to determine limits for application rates.

Agricultural soils are tested routinely for soil pH, organic matter, and the primary nutrients phosphorus (P), potassium (K), and nitrogen (N). In some regions, soils are also routinely tested for the often referred to as secondary nutrients such as calcium (Ca), magnesium (Mg), and sulfur (S) and for others referred to as micronutrients because they are required in very small amounts by crops such as boron (B), copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), and zinc (Zn). Soils receiving waste biosolid

materials from industries, crops, animal products, or drinking water processing plants are also tested for elements such as arsenic (As), cadmium (Cd), nickel (Ni), lead (Pb), mercury (Hg), and selenium (Se) among others.

Excessive N and P applications to agricultural fields and ineffective nutrient, soil, and water conservation practices are increasing nutrient pollution of water in many regions of the world. Although the basic concepts of soil testing apply to all nutrients and other elements, the dynamics in the soil and mechanisms of loss to groundwater and surface water differ radically for some nutrients. For example, P is included with other elements in a group with relatively low mobility in soils (Ca, Cd, Cu, Fe, Mg, Mn, Mo, Ni, Pb, and Zn among others). Nitrogen, especially in the nitrate form, is included in a group of nutrients and elements with greater mobility (which include B, Cl (chlorine), S, and others).

This chapter focusses mainly on commonly used soil testing for crop-availability of the plant nutrients N and P, which are also nutrients whose excess impairs many surface waters worldwide. Important concepts for these nutrients and many others include taking representative soil samples from fields, use of a correct soil sampling depth, determination of the meaning of a soil-test value for crop production and use in tools for risk loss assessments, and soil-test quality. Soil testing for research, soil quality and health, and elements harmful to human health are beyond the scope of this chapter.

Soil sampling for soil testing

For a soil testing program to be effective, besides laboratory quality control, soil samples should be collected in a cost-effective manner and should accurately represent the nutrient concentrations in the area of interest. Sampling is a critical component of the soil-testing process because there is often considerable spatial variation in the nutrients of most fields and usually represents the largest single source of error in soil testing. Sampling protocols must account for the large diversity in magnitude, structure, and spatial scale of nutrient variation present in agricultural fields and other ecosystems.

Soil nutrient variation within a crop field may be due to soil formation or management factors. Factors such as landscape position and soil parent material can cause great changes in soil texture, organic matter, drainage, and other properties. These properties affect nutrient concentrations directly through their influence on the amount of plant-available nutrient or indirectly through crop yield potential and, thus, the nutrient removal by crops. Variation caused by long-term history of management and land use practices overlays that associated with soil-formation factors. The cumulative effects of nonuniform manure or fertilizer application are sources of potentially considerable variation in soil-test results. Proximity to livestock confinement areas, feed storage areas, and field boundaries are additional examples of historical factors causing great variability in many fields. In addition, significant small-scale variation over distances as small as a few centimeters or meters usually is present in fields with long histories of cropping and fertilizer or manure applications, especially when nutrients have been applied using band methods. The challenge in these situations is to determine effective methods to delineate sampling areas within a field and the number of cores or borings needed for each composite sample to account for small-scale variation appropriately.

A variety of systematic and zone sampling approaches have been developed in different regions. The development of accurate and reliable global positioning technology, affordable geographic information systems, and variable-rate application equipment have led to widespread use of site-specific soil sampling approaches in Canada, the United States, Europe, Australia for example. These sampling approaches typically are used to generate a soil fertility map to serve as an input to computer-controlled equipment for applying varying rates of one or more materials when precision agriculture and variable-rate technologies are used. One such approach is zone sampling, which is essentially a stratified sampling, by which field subregions with more homogeneous properties than an entire field are delineated. Landscape position, soil color, soil mapping unit, crop growth differences, soil electromagnetic inductance, and other soil or crop canopy properties are assessed by direct or remote sensing methods. Aerial images are examples of factors often used to help define sampling zones. The basic assumption for these sampling procedures is that soil-test levels or fertilizer use efficiency are more homogenous within these zones than across an entire field.

This assumption, however, sometimes does not hold especially when land has had a long history of fertilization or manure application and when soils or landscape forms differ little within a field. Therefore, another site-specific approach that has gained adoption in some countries involves grid soil sampling, by which soil-test patterns in a field are determined by a dense, systematic sampling of composite samples. A grid size of approximately 1 ha is a common sampling approach today in the United States, and cores or borings for composite samples are collected from each entire area (cell sampling) or from a very small section (point sampling) positioned systematically or randomly. Small-scale variability of P and K is so extreme in some fields with long histories of fertilizer or manure application that accurate within-field soil fertility mapping is very difficult and sometimes economically unfeasible.

Many articles and book chapters about soil sampling have been written since the 1940s but much uncertainty still exists on how best to perform site-specific soil sampling and generate accurate soil fertility maps. Recent useful research results and concepts for soil sampling for crop production or risk assessments of P loss using precision agriculture technologies have been addressed in recent years by Mueller et al. (2001), Bianchini and Mallarino (2002), Kitchen et al. (2003), Fridgen et al. (2004), Mallarino and Witty (2004), Flowers et al. (2005), Mallarino et al., (2007), Pennock et al. (2007), Sawchik and Mallarino (2008), and Lawrence et al. (2019).

Soil-test values also change significantly with depth. This results from a combination of soil-forming and management factors and from the different mobility of nutrients in soils. The elements with lower mobility (see above) tend to accumulate near the application point (often the shallowest soil layers) because they are more strongly retained by soil constituents than the more mobile nutrients. The tillage system and method of application greatly influence vertical nutrient stratification. For example, the

significant stratification of both P and K in no-till soils is well known, but subsurface nutrient application methods can reduce their concentration near the soil surface. Thus, the proper depth for soil sampling and its consistency are important considerations (James and Wells, 1990; Lawrence et al., 2019). Variation in soil-test results can also result from differences in sampling depth. Soil samples should be collected at the same depth used in the calibration research that serves as the quantitative basis for interpretation of the soil-test and nutrient recommendations. Typically, this is a depth of 15–20 cm for the relatively immobile nutrients (such as P, K, Ca, Mg, Cu, Fe, Mn, Zn) and 30–60 cm for the more mobile nutrients (such as nitrate-N). However, the most appropriate soil sampling depth varies with the objective of the soil testing. For example, a sampling depth of 15–20 cm is usually the best to assess nutrient sufficiency for crops or nutrient loss with subsurface drainage, but a shallower sampling depth is often better to predict loss of P loss with surface runoff especially with no-till management or pastures (Vadas et al., 2005).

Soil-test extractants and methodologies

Phosphorus soil tests

Soil tests for P and other elements have been developed based on an understanding of the chemical forms in which the elements exist in the soil and empirical work. In most soils, P is primarily associated with aluminum (Al), Fe, and Ca. Phosphorus precipitation and (or) adsorption to Fe and Al oxides generally predominates in acid ($\text{pH} < 7.0$) to neutral soils, whereas reactions with Ca predominate in soils with significant amounts of calcium carbonate. The degree and strength to which P is bound in soils are largely determined by the amount and types of Fe and Ca compounds present and by other soil properties such as pH, organic matter, clay mineralogy, and the amount of P currently present in the soil. The influence of Fe increases and that of Ca decreases as rainfall, temperature, and weathering increase. These factors are also important in determining the plant availability and solubility of other immobile elements.

Phosphorus soil-test methods for agronomic use employ dilute strong acids, dilute weak acids, complexing ions, and (or) buffered alkaline solutions (Beegle, 2005). Most tests have been developed to reflect the soil properties related to P sorption that predominate in a region. For example, the Bray P-1 test was developed for use in the acid to neutral soils of the north-central region of the United States, the Olsen test (or sodium bicarbonate) was developed primarily for use on calcareous soils of the same region, and the Mehlich-1 test was developed for the low cation-exchange capacity and highly weathered soils common to southeastern regions. The Mehlich-3 extractant, although developed in the 1980s, has been rapidly adopted in the US and many other countries during the last decade because it is suitable for a wider range of soil properties than other P or K tests and for other nutrients (such as Ca, Mg, Fe, and Zn). Although the results of the different soil P tests are often strongly correlated for soils with similar properties, the actual quantities extracted can differ greatly for soils with specific characteristics. For example, the Mehlich-3 test extracts 1.5–2 times the amount of P as the Mehlich-1 and Olsen tests. These observations highlight the importance of understanding the meaning of a soil-test value and proper calibration.

In the United States and most European countries, regulatory initiatives have been established to mitigate water-quality problems associated with N and P water pollution. Agronomic soil-test methods designed to assess plant-available nutrients are often used for environmental purposes. However, increasing concerns about nonpoint-source P pollution from agriculture has prompted questions about the suitability of agronomic soil P tests for environmental purposes. An effective environmental soil test should measure the nutrient forms most important to eutrophication or other negative environmental impacts. Eutrophication is a process whereby water bodies, such as lakes, estuaries, or slow-moving streams receive excess nutrients that stimulate excessive aquatic plant or algal growth. This enhanced growth reduces dissolved oxygen in the water when dead plant or algal material decomposes, which causes ecosystem imbalances and may promote growth of toxic bacteria and unpleasant odor. Several soil tests have been proposed as environmental tests for soil P because they may provide better estimates of dissolved P delivery to water resources (Kovar and Pierzinsky, 2009). Two of these tests are being used extensively. One test based on FeO-impregnated paper uses a sink approach to extract soil-bound P that is most likely to be available to aquatic organisms. The other test is based on weaker desorption reactions and uses either deionized water or a diluted calcium-chloride solution to extract soil P. Current research indicates that usually there are linear and similar relationships between either agronomic or environmental soil P tests and dissolved P in surface runoff or subsurface drainage. As an example, Fig. 1 shows relationships between total P in the drainage discharge to a lake from five basins and the mean soil-test P of the basins measured by four soil test methods (Klatt et al., 2003). In this case, soil P measured by agronomic tests specifically developed to estimate soil P sufficiency for crops (Mehlich-3 and Olsen) shows approximately similar increasing linear relationships to P measured by so-called environmental P tests Fe-oxide coated filter paper and water-extractable P.

Indices of soil P saturation or environmental soil P tests tend to relate better to dissolved P loss in regions with extremely large soil P concentrations. In these cases, the dissolved P loss sometimes increases exponentially with increasing soil P or shows a discontinuous relationship with an initially flat response and then linear increase after a change point (Maguire and Sims, 2002; Sharpley et al., 2003).

Soil-test P results from agronomic or environmental soil tests are seldom used as a single metric to estimate P losses from fields or loads to water resources. The most important reason is that a certain concentration of an element in the soil may have different impacts on the environment depending on the amount retained by the soil and potential delivery to environmentally critical areas, which can be effected by a variety of mechanisms. For example, soils with high clay content have a greater sorption capacity for P (and for other immobile elements) than coarse-textured soils, and less P is delivered as the distance from the source to channeled water flow increases. Establishment of nutrient loads that can result in unacceptable water-quality degradation will depend on

Fig. 1 Relationship between total P concentration in water discharge and soil-test phosphorus measured with four soil P tests for five basins of the Iowa Clear Lake agricultural watershed. Adapted from Klatt JG, Mallarino AP, Downing JA, Kopaska JA, and Wittry DJ (2003) Soil phosphorus, management practices, and their relationship to phosphorus delivery in the Iowa Clear Lake agricultural watershed. *Journal of Environmental Quality* 32: 2140–2149.

factors such as the distance to a sensitive water body, the effectiveness of transport pathways for water and either total or dissolved P fractions, and socioeconomic factors involving land or water use. Therefore, a critical soil-test concentration value or range, often referred to as a threshold, is unlikely to be found for nutrient impacts on the environment and is seldom recommended, whereas risk assessment tools, such as P indices, are used to assess risk of P loss from fields.

A P index is often not a full-blown model of P loss and transport but a more quantitative practical tool that considers soil-test values with other site-specific factors (such as hydrology, nutrient management, water body proximity and sensitivity to nutrient inputs) to determine the potential environmental risk of P concentrations in a field or parts of fields (Sharpley et al., 2003). The Iowa P Index, for example (Mallarino et al., 2002) includes the components total P loss with erosion, dissolved P loss with surface runoff, dissolved P loss through subsurface drainage, and surface source factors (soil-test values as well as fertilizer and manure application rates, methods, and timing) and transport factors (such as soil erosion, surface runoff, subsurface drainage, and distance to streams or water bodies).

Nitrogen soil tests

The cycling of N in soils is different from other nutrients and requires a different soil-testing approach. More than 97% of N in soils is present in organic forms and is converted to inorganic forms available to plants mostly through microbial activity. The rate of N release from organic to inorganic forms is difficult to predict because it depends on temperature, moisture, aeration, type of organic matter, soil pH and many other factors. The predominant inorganic end-result of mineralization is nitrate-N. This form of N is highly mobile in soils, and is subject to loss by leaching and to gaseous losses through denitrification. Because of these factors, N fertilizer recommendations for crops are not based solely on soil organic matter and frequently are made on the basis of crop yield potential coupled with an N-credit system and less frequently on the basis of soil testing. The N-credit system is based on empirical information of the effects of previous crops, several soil properties, and climate on crop response to N fertilization.

Soil organic matter or N fractions, mineralizable soil N, preplant soil nitrate tests, and postemergence or pre-sidedress soil nitrate tests have been investigated and proposed for a long time to estimate maize (*Zea mays* L.) N needs in the United States and other countries. A soil test has been proposed that estimates soil N supply potential for adjustments to N recommendations; it estimates ammonium N plus a labile pool of soil N that could mineralize during the growing season (Khan et al., 2001; Mulvaney et al., 2001). However, evaluations with crop yield response have been inconsistent or shown to be an unreliable diagnostic tool and so is seldom used (Laboski et al., 2008). In low-rainfall areas, where the potential for nitrate leaching is minimal and irrigation is controlled, the amount of nitrate-N in the soil profile before planting maize can be credited directly against the N needs of the crop. In more humid regions, measurements of soil profile nitrate or ammonium before planting have been unreliable for predicting the N needs of maize. However, nitrate-N testing early in the growing season has been shown to provide an index of the soil's N-supplying capability for maize. Soil samples for the pre-sidedress soil nitrate test are collected from a 0–30-cm depth after

planting the crop and before plants reach a height of 15–30 cm. Recent research across several states of the US Midwest region showed that the pre-sidedress soil nitrate test (a 30-cm sample at the V5 to V6 growth stage) was the single best predictor of maize N needs and the economic optimum N rate, and that combinations of this test with preplant profile soil nitrate or potentially mineralizable soil N tests improved the prediction only marginally (Clark et al., 2020). However, all methods produce different measurements of soil nitrate and there is uncertainty for environmental assessments because nitrate from soil samples often does not relate well to the nitrate that moves through the soil profile and is measured with lysimeters (Darrouzet-Nardi and Weintraub, 2014).

Advances in electronics and sensing technologies have resulted in intensive current research for their implementation in N or nitrate soil testing in the field or laboratory. Sensors of different types have been used successfully to measure soil moisture, organic carbon or organic matter, and salts. Recently there were advances in applications for soil nitrate testing but additional research is needed before these methods can substitute for conventional extraction laboratory methods (McBride, 2021; Zhu et al., 2021). Interpretation of the soil nitrate tests is usually complemented by consideration of the previous crop, rainfall during a 2–4 week period before or after collecting the samples, and soil properties that influence nitrate leaching. As with all soil tests, local or regional field calibrations are conducted to determine critical ranges for soil nitrate concentration.

As was discussed for P, N or nitrate, soil tests are seldom used alone as an index of potential losses to water resources and most often regulation is based on rates of N application and or time of application. The use of N indices is less widespread or accepted compared with P indices. For example, the federal Natural Resources Conservation Service (NRCS) of the United States Department of Agriculture (USDA) has proposed a nitrogen leaching index but few states have implemented it or modifications to guide agronomic practices or regulations.

Calibration of soil tests for crop production

Soil tests seldom extract the total amount of nutrients or elements in a soil sample. Soil tests have been developed to measure a fraction of the total soil nutrient concentration that correlates with plant growth. Interpreting a soil-test value requires an understanding of the impacts on test results of the extractant used, method of soil sampling, sample handling, and the intended use for the result. The amount of nutrient measured by various soil tests can vary widely depending on the extractant used. Important extractant properties include the concentration of the chemical compounds and the reaction time with the soil. The method used to measure the nutrient after extraction may be important for some nutrients. For example, colorimetric methods usually measure only orthophosphate P while other methods may also measure other forms of P. The same soil test may also measure widely different amounts of nutrients in soils with contrasting chemical and (or) mineralogical properties. Extractants used and interpretations of results often vary depending on soil properties and the purpose of soil testing (for example, measurement of total, soluble, or plant-available concentrations).

A soil-test method useful for predicting crop response to fertilization should produce values that are well correlated with plant nutrient uptake or yield. Greenhouse and field research is conducted to determine which soil-test extractant may be best suited for a given combination of soil, crop, and growing conditions. Accurate interpretations of soil-test results and appropriate fertilizer recommendations require that the relationship between the amount of a nutrient measured by a given soil test and the crop response to the added nutrient must be known. The process of determining the probability of crop response at a given soil-test value is known as soil-test correlation and the process of determining the amount of nutrients to be applied for desired yield levels is known as calibration; however, sometimes both words are used for either process. The correlation and calibration procedure usually involves growing a crop in soils that are representative of the region on which the test will be used for the application of various fertilization rates. The soils should have a broad range of soil-test values that include deficient, optimum, and above-optimum values.

The crop yield response can be expressed as an absolute value or as a value relative to the yield achieved without nutrient addition. At low soil-test values, crop yield is limited by nutrient deficiency. As soil-test values increase, yield increases at a reduced rate until a maximum yield value. At higher levels, there is no longer a relationship between the soil-test values and yield. The maximum yield value can remain approximately constant for a wide range of soil-test values or can decrease at excessively large nutrient concentrations. The soil-test value at which crop growth or yield reaches a maximum is called the soil-test critical concentration. This is the soil-test value that best separates soils where a positive crop yield response to an added nutrient is likely from those soils where a response is not likely. Various mathematical models can calculate different critical concentration values and some models are asymptotic to a maximum. For example, Fig. 2 shows the relationships between the relative yield response of maize and the amount of soil P extracted by four methods (Mallarino et al., 2005). The figure shows the fitted line for a linear-plateau model and the corresponding estimated critical concentration, but the authors indicated that the critical levels estimated by Cate-Nelson for linear-plateau and quadratic-plateau models ranged from 13 to 28 mg P kg⁻¹ across the four test methods. There is no reasonable agronomic consideration that justifies a single critical concentration. Moreover, economic considerations suggest that maximum economic yield perhaps should be the basis for determining critical concentrations instead of a physical maximum. Thus, critical concentration ranges usually are determined by using a combination of models and a variety of both agronomic and economic considerations. The soil-test response curve often is used to divide soil-test levels into several categories such as very low, low, optimum, high, or excessive.

Fig. 2 Relationships between relative crop yield response and soil-test P values by four methods. The gray arrow and point indicate results for a highly calcareous soil. Adapted from Mallarino AP and Atia AM (2005) Correlation of a resin membrane soil phosphorus test with corn yield and routine soil tests. *Soil Science Society of America Journal* 69: 266–272.

A thorough understanding of crop response to nutrients and factors such as sampling date (season of the year), sampling method (mainly sampling depth), method of nutrient application (for example, band or broadcast), and application timing are needed to interpret soil-test results correctly. Other factors can also influence crop growth (climatic factors, plant population, concentrations of other nutrients in the soil, and crop cultivars among others). These factors may influence crop growth without affecting the amount of nutrient needed to produce a certain yield or they may interact with nutrient concentrations in the soil. Climatic factors, especially soil temperature, and both total rainfall and distribution during the year, are especially important for nutrients that are highly mobile in the soil, such as nitrate-N, B, Cl, and S. High nutrient mobility results in more difficult soil-test calibrations and introduces more uncertainty when interpreting soil test results. The temporal variation during the year for the more immobile nutrients can also be significant in coarse textured soils because of leaching from the topsoil to deeper layers in the soil profile or to groundwater. It is possible that advances in the near future from research on in-situ sensor technologies can account better for temporal variation in soil nutrient concentrations.

Quality of soil testing

The quality of a laboratory soil-test result can be assessed on the basis of bias and precision. Bias refers to the deviation of the analytical result from the true value and measures the accuracy of the result. Precision refers to the reproducibility of a given test value. A soil-testing laboratory could have good precision for a specific procedure but have bias in its results. Guidelines for laboratory soil test quality control and quality assurance are provided by institutions in most countries. A primary means of evaluating soil-test quality procedures as well as laboratory performance is through comparisons of the tests performed on well-mixed sub-samples of the same soil at different laboratories. In North America, a voluntary proficiency testing program developed by the Soil Science Society of America was launched in the early 2000s to improve the quality of soil testing for agronomic purposes (the North American Proficiency Testing Program, NAPT, <https://www.naptprogram.org>). Results from this program indicate that, for example, the average variability of P tests is approximately 10–15% and that 65–70% of participating laboratories produced results within this level of variability. Variability is lower within any given laboratory, with precision levels for the P tests discussed are roughly 5–10%.

Summary

Soil testing has been an important diagnostic tool for determining the nutrient needs of plants for decades. Thus, soil testing is widely accepted and used in most advanced crop production areas of the world to determine fertilization needs for crops. Soil testing also has long been used to assess excess accumulation of harmful elements in the soil. More recently, soil testing for N and P

began to be used as part of the complex tools to assess the risk of loss from agricultural fields to water resources. This chapter focused mainly on testing soils for the plant nutrients N and P, which are also nutrients whose excess loss from fields impairs surface waters worldwide. Important concepts discussed, which apply to most nutrients, included taking representative soil samples from fields, use of an appropriate soil sampling depth, which often changes for different nutrients and management systems, use of proper calibration with crop yield response to provide a reliable meaning for the soil-test value to determine recommended nutrient application rates for crop production, and the role of soil testing in complex tools to assess the risk of nutrient loss from fields to water resources and water quality impairment. The applicability of different soil tests for a nutrient varies greatly across soils and regions of the world. In addition, the soil-test values that may indicate sufficient concentrations for crops or excessive levels that are likely to result in excessive nutrient loss to water resources also varies greatly. Therefore, local research is essential for the correct development and implementation of new soil tests and soil testing programs.

Abstract

Total content of metals in the soil does not correlate well with the uptake by plants. Therefore, extraction methods have been developed to estimate the so-called bioavailable fractions, including single extraction, sequential extraction and DGT (diffusive gradients in thin films). Each extraction method has its advantages and pitfalls, and is suitable for different situations. However, no extraction method can extract the 'true bioavailable' fraction of metals in the soil because of the complexity of binding forces between the metal ions and soil components. At best, chemically extractible metal content can be a good estimate of the bioavailable content of the metal.

Key points

- Metal extraction methods can provide estimates of the bioavailable content of metals in the soil to a certain extent.
- The 'true bioavailable' fraction of the metals cannot be measured, because uptake and accumulation of the metals are influenced by numerous factors related to the soil, plants and environment.
- Chemical extraction of the metals may be single step or sequential.

Introduction

Among all soil contaminants, potentially toxic metal(loid)s, often referred to as heavy metals (Duffus, 2002), have become increasingly the focus of urgent environmental concern worldwide. Metal(loid)s in soils are bound with various soil components (such as minerals, organic matter, iron oxides, manganese oxides, etc.) involving different binding forces (such as electrostatic attraction, covalent bond, Van der Waals force, etc.). Consequently metal(loid)s exist in numerous forms in soils, referred to as fractions, with different activity and biological availability. The metals in some fractions, such as water-soluble and exchangeable fractions, are highly bioavailable to plants, but others (such as residual fractions) are much less available. Toxic metal(loid)s with strong bioavailability threaten biota more directly than do the other fractions. Numerous methods have been developed to assess the bioavailability of metals in the soil. Although there is still no unanimity in the adoption of a single method for assessing soil contamination by metals, some metal extraction methods are widely used worldwide.

Metal extraction methods

Chemical extraction is used for investigating the fractions of potentially toxic metals and other elements in the soil. There are two main groups of metal extraction methods, single extraction and sequential extraction; both are used to evaluate the availability of metals in soils.

Single extraction

Single extraction involves a single extraction reagent (generally a ligand, diluted acid or salts) or a compound extraction reagent. These tests are usually conducted to study the eco-toxicity and the bioavailability of metals or other elements in the soils to estimate the potential phytotoxic effects to plants and the nutrient supplying capacity of the metals in soils. The extraction reagents can be classified into several groups, such as ligands, neutral salts, diluted mineral acids and organic acids, etc., based on their chemical properties.

Ligands

The diethylene triamine pentaacetic acid (DTPA) and ethylenediamine tetraacetic acid (EDTA) are two ligands widely used in soils to complex with readily available metals, such as copper (Cu), cadmium (Cd), lead (Pb) and zinc (Zn), thereby removing them from the soil organo-mineral complex.

Diethylene triamine pentaacetic acid, DTPA

The DTPA soil test was developed by Lindsay and Norvell in 1967 to extract the available Zn, iron (Fe), manganese (Mn), or Cu in near-neutral and calcareous soils (Lindsay and Norvell, 1978). This method is now widely used in many soils. The extraction solution consists of 0.005 M DTPA, 0.01 M CaCl_2 , and 0.1 M triethylamine (TEA) at $\text{pH} = 7.3$ (Lindsay and Norvell, 1978). In the extraction solution, DTPA acts as a chelating agent for the metals, triethylamine (TEA) is a buffer (pK_a (negative log of the acid dissociation constant, K_a) = 7.8), Ca^{2+} (calcium) maintains the slight alkalinity with TEA and also replaces metal cations from the soil surface. According to the protocol given by the Standards, Measurements and Testing Program (SMTP, formerly BCR) of the European Commission (1998), the DTPA extraction procedure is as follows: 10 g soil sample is mixed with 20 mL of 0.005 M DTPA solution, and then shaken for 2 h at room temperature ($20 \pm 2^\circ\text{C}$). The DTPA has a strong ability to complex metal cations and to release them into soil solution. The different binding strengths of DTPA with different metal cations largely control the extraction efficiency for these metals. The binding strength between the soil and the metals also affects the extraction efficiency. The DTPA-extraction is suitable for extracting Zn, Fe, Mn, Cu, Pb and Cd from the soil, whereas it is less suitable for extracting nickel (Ni) and chromium (Cr).

Ethylenediamine tetraacetic acid, EDTA

Ethylenediamine tetraacetic acid is widely used as a complexing agent because of its strong complexing ability with metal cations. The EDTA can draw out metals from exchange sites of both organic and inorganic groups, and dissolve calcareous deposits through its complexation with metal ions or Ca^{2+} and Mg^{2+} (magnesium). The 0.05 M EDTA solution ($\text{pH} = 7.0$) is commonly used as an extractant. In 1998, SMTP of the European Commission formulated an EDTA extraction procedure, including preparation of the extractant. According to the SMTP annex, the 0.05 M EDTA extraction solution ($\text{pH} = 7.0$) is prepared by adding 146.12 g of EDTA free acid to 800 mL distilled water and partially dissolving it by stirring in 130 mL of saturated ammonia solution (Quevauviller, 1998). For the extraction, a 5-g soil sample is transferred to an extraction bottle in which 50 mL of 0.05 M EDTA has been added (Sahuquillo et al., 1998). The mixture is shaken for 1 h at room temperature ($20 \pm 2^\circ\text{C}$). The EDTA extracts not only exchangeable fraction of the metals, but also carbonate- and organically-bound fractions. The extraction efficiency of DTPA and EDTA is greater than that of the un-buffered salt solutions because of their strong complexing ability.

Salts

Some salts, such as calcium chloride (CaCl_2), ammonium acetate (NH_4OAc), ammonium nitrate (NH_4NO_3), potassium nitrate (KNO_3), magnesium chloride (MgCl_2), and sodium nitrate (NaNO_3) are used as extractants to evaluate bioavailable metals in soils. In most cases, the extraction solutions of these salts are un-buffered. They are more suitable for predicting the plant available metals than some extractants with stronger extraction capacity and diluted acids. The metals in the fractions extracted with the neutral salts, such as 0.01 M CaCl_2 or 1 M NH_4NO_3 , often show better correlations with plant contents of the metals because of the chemical similarity between the extraction and soil solutions.

Calcium chloride (CaCl_2)

In the 1970s, Mn and aluminum (Al) extracted with 0.01 M CaCl_2 from acidic soils showed strong correlations with their toxicity to plants (Houba et al., 1996). This soil test is applied to extract bioavailable fractions of metals (such as Cd, Ni, Zn) from soils. Other concentrations of CaCl_2 , such as 0.1 M, have also been used to extract metals, which also showed good correlations with their plant contents. The 0.01 M CaCl_2 extraction is both practical and environmentally friendly because this extraction solution matched with the soil solution in terms of the composition and concentration of ions. The metals extracted with 0.01 M CaCl_2 are mainly exchangeable fractions, which are readily bioavailable to plants. The amount of 0.01 M CaCl_2 exchangeable metals is mainly controlled by metal desorption from the soil which is affected by the extraction solution. The electrostatically adsorbed metals can be replaced by Ca^{2+} in the extraction solution, whereas it is generally difficult to desorb chemically adsorbed metals by 0.01 M CaCl_2 . Because 0.01 M CaCl_2 is milder than other extraction solutions, such as EDTA, DTPA or dilute acids, the quantity of metals extracted by 0.01 M CaCl_2 solutions is less than that extracted with complexing solutions or diluted acids.

Ammonium acetate

Ammonium acetate solution (1 M NH_4OAc , pH = 7.0) is commonly used to extract exchangeable cations from the soil (Ure et al., 1993). This solution is usually buffered at pH 7 to avoid the dissolution of carbonate at low pH. For ammonium acetate, NH_4^+ replaces readily exchangeable metals and acetate acts as a ligand to form complexes with the metals. The complexes are then released from the soil into the solution. Specifically sorbed cations, which are less readily exchangeable, are difficult to displace by NH_4^+ but can be replaced by H^+ (hydrogen). Ammonium acetate is also acidified to pH = 5 to dissolve carbonates and release carbonate-bound metals into the soil solution. The large salt concentration (1 M NH_4OAc) in the extracts causes difficulties for determinations using the atomic absorption spectrophotometer or inductively coupled plasma mass spectrometry (ICP-MS). The amount of Cd extracted by the 1 M NH_4OAc (pH = 7.0) procedure is less than that by HCl, EDTA, DTPA, etc.

Diluted mineral acid

The most commonly used diluted acid for metal extraction is diluted hydrochloric acid (HCl). Diluted nitric acid (HNO_3) has a particular advantage because the nitrate anion (NO_3^-) has little complexing capacity for the metal cations. Thus the anion in HNO_3 does not interfere with metal extraction by acid dissolution.

Diluted HCl is one of the most widely used extractants for releasing the acid-soluble fraction of the soil. It can replace exchangeable metal cations by its H^+ ion, dissolve calcareous bound metals through dissolution, and form soluble complexes with metal cations by its Cl^- ion, a strong ligand for metal cations (Leleyter et al., 2012). The 0.1 M HCl is the most commonly used concentration of HCl for metal extraction, although other concentrations such as 0.5 M are also used. It has been reported that bioavailable Pb may be underestimated using a low concentration of HCl (0.1 M) because Pb^{2+} readily precipitates as PbCl_2 (Wei et al., 2005). On the contrary, 0.1 M HCl overestimates bioavailable Cu in the soil because it promotes the release of Cu bound with some Fe or Mn oxides (Yu et al., 2004). The Fe/Mn oxides-bound Cu is not readily available to plants under field conditions, therefore the 0.1 M HCl extractable metal content is generally poorly correlated with the metals taken up by plants. More concentrated solutions of HCl are unsuitable for estimating bioavailable soil metal content because sparingly soluble metals of little significance for plant absorption may be solubilized.

Low molecular weight organic acids (LMWOA)

Low molecular weight organic acids (LMWOA) include several organic acids, such as oxalic, acetic, malic, citric, and succinic acids (Abollino et al., 2011). These acids may be produced by the decomposition of organic matter or plant root exudates. The LMWOA extract metals in soil by a combination of acid dissolution due to their acidity and complexation with the metal cations due to their functional groups, which include carboxyl, phenolic, and amino groups. Ligands of the acids may also substitute the metalloids (such as arsenic) bound with the soil surfaces by ligand exchange. The Fe^{3+} and Mn^{4+} in Fe/Mn oxides may also be complexed by the ligands of LMWOA, resulting in dissolution of the oxides, which leads to the release of the metals bound with the oxides. The gradual disintegration of iron oxides caused by LMWOA may play an important role in releasing arsenic (As). The LMWOA are weaker metal extracting agents than complexing reagents. Furthermore, the extraction capacity differs between acids. Oxalic acid has a greater capacity to mobilize Cu, Zn, Pb, As, Fe and Mn than does acetic acid. The reductive dissolution of LMWOA also plays an important role in the dissolution of iron oxides in the presence of oxalic acid.

Complex extraction

A complex extraction solution, designed to simulate the soil rhizosphere, has been developed to determine the bioavailability of trace metals. The extraction solution based on a mixture of EDTA and NH_4OAc was originally proposed by Lakanen and Ervio (1971). The complexation of EDTA and acetic acid is considered to simulate the complexation behavior of root exudates, and NH_4^+ (ammonium) may desorb the exchangeable soil fraction (Meers et al., 2007).

The Toxicity Characteristic Leaching Procedure (TCLP) is the US EPA's method for testing toxicity of metals in the soil, which involves extraction with diluted acetic acid and sodium hydroxide (Abollino et al., 2011). It is often used as an operational procedure to evaluate the leaching of metals before the reuse of contaminated land. However, some studies have raised the potential limitations of TCLP in evaluating cementitious wastes because of the high final pH of the leaching solution, therefore, the release of metals may be hindered (Halim, 2003; Lu et al., 2019; Malviya and Chaudhary, 2006).

Sequential extraction

Sequential extraction combines several continuous extraction steps and is commonly used to assess the mobility, availability, distribution and potential toxicity of metals in soils, sediments, and other solid materials (Zimmerman and Weindorf, 2010). The first sequential extraction procedure on metal fractions was proposed by Tessier in 1979. In 1987, the Community Bureau of Reference (BCR), Europe Commission, proposed a new sequential extraction procedure, which was a significant advance in sequential extraction following the Tessier procedure. The BCR extraction procedure aimed to harmonize the existing extraction procedures. In 1993 a standardized three-step sequential extraction protocol (SEP) was proposed, and is known as BCR SEP. The theoretical basis for SEP is that the metals are adsorbed or bound with solid surfaces through various binding forces, and can be extracted in the order of their solubility using different extracting agents and under different conditions. The most soluble fraction is the first to be removed from the soil.

The Tessier procedure

Tessier's protocol divides soil metals into five operationally defined fractions in the order of extraction: exchangeable, carbonate bound, Fe and Mn oxide bound, organic matter bound, and residual, respectively (Tessier et al., 1979). The Tessier procedure is the most widely used extraction method for the fractionation of metals in the soil. The exchangeable fraction is contributed by the metals associated with soil particle surfaces by electrostatic mechanisms. The metals in this fraction are easily exchanged with other cations and easily absorbed by plant roots. This fraction is extracted with MgCl_2 (pH = 7.0) solution. One gram of a soil sample is mixed with 8 mL 1 M MgCl_2 (pH = 7.0) in a 50-mL centrifugation tube. The mixture is agitated at room temperature for 1 h. After agitation, the supernatant and the soil residue are separated by centrifugation. The carbonate-bound fraction is extracted with NaOAc solution, whereby 8 mL of 1 M NaOAc (pH = 5.0) is mixed with the soil residue of the exchangeable fraction. The mixture is shaken for 5 h at room temperature, and centrifuged to separate the supernatant and soil residue. Metals bound to Fe and Mn oxides are particularly susceptible to reducing conditions. The Fe—Mn oxides bound fraction is extracted with 0.04 M $\text{NH}_2\text{OH—HCl}$ in 25% (v/v) HOAc (pH = 2) at 96 °C for 6 h with occasional agitation. The organic-bound fraction is extracted with 0.02 M $\text{HNO}_3 + \text{H}_2\text{O}_2$. The soil residue of Fe—Mn oxides bound fraction is mixed with 3 mL of 0.02 M $\text{HNO}_3 + 5$ mL of 30% (m/v) H_2O_2 (pH = 2). The mixture is heated to 85 ± 2 °C for 2 h with intermittent agitation. A second 3-mL aliquot of 30% H_2O_2 (pH = 2 with HNO_3) is then added and the sample heated again to 85 ± 2 °C for 3 h with intermittent agitation. After cooling, 5 mL of 3.2 M NH_4OAc in 20% (v/v) HNO_3 is added to the tube, and the mixture diluted to 20 mL and agitated for another 30 min. The addition of NH_4OAc is to prevent adsorption of extracted metals onto the soil. In the Tessier extraction procedure, after agitation, the mixture is centrifuged to separate the supernatant and the soil residue. The residue from the organic-bound fraction is digested with an HF—HClO_4 mixture. Since the introduction of the Tessier procedure, some modifications have been proposed (Fig. 1).

Although the Tessier SEP has been widely used, there are some pitfalls in the procedure. The first is selectivity of the extracting reagents. The fractions are given names that strongly suggest their chemical form in soil. However, the metals extracted by the various extracting solutions do not represent exactly the fraction bound with the specific components. In the Tessier procedure, MgCl_2 is used to exchange the metal cations adsorbed on soil surfaces with Mg^{2+} . However, more metal cations would be released due to the formation of metal–chloride complexes, displacing the equilibrium in favor of soluble forms. The 1 M NaOAc (pH = 5.0) has been found to dissolve portlandite ($\text{Ca}[\text{OH}]_2$) and brucite ($\text{Mg}_3[\text{OH}]_6$). When the residue of the exchangeable fraction is extracted with 1 M NaOAc (pH = 5.0), a decrease of 2 pH units occurs. This reduction of 2 pH units covers the pH range of the adsorption edge of the majority of the metals, resulting in an overestimate of carbonate-bound metals. The pH range (5–6) is conducive to Mn oxyhydroxide dissolution, so the addition of NaOAc (pH = 5.0) may dissolve manganous and ferrous oxides, leading to metal release from components other than carbonates. Hydrogen peroxide (H_2O_2) is used for the organic-bound fraction. It was found that it only partially dissolved organic materials and was not selective enough. The H_2O_2 solution (pH = 2) also dissolves manganese oxyhydroxides, amorphous iron oxyhydroxides, and sulfides, resulting in an overestimate of the organic-bound fraction (Beckett, 1989; Hass and Fine, 2010).

Another problem is redistribution of the extracted metals. When the exchangeable fraction is extracted, the metals from exchange sites may be adsorbed to specific sorption sites. Soil homogenization (by grinding and sieving), and extraction procedure harmonization (i.e., shaking) can promote specific adsorption of some electrostatically adsorbed metals (Hass and Fine, 2010).

Fig. 1 Tessier sequential extraction procedures used for operational speciation of metals.

Neutral salts that are used to extract the exchangeable fraction result in coagulation and precipitation of organo-metal complexes, leading to an underestimate of the soluble component. During Mn—Fe oxyhydroxide extraction using acid ammonium oxalate, oxalate-metal precipitates may form, resulting in underestimates of the metals in this fraction. Some studies on the Tessier procedure showed that metals in exchangeable, carbonate-bound, and Fe and Mn oxide bound fractions would be underestimated while that for the organic-bound and residual fractions would be overestimated, because metals extracted from the first three fractions were redistributed to the following two fractions.

The above limitations lead to ambiguity of the meaning of the fractions of metals, which makes it difficult to explain them. It must be clear that these fractions are operationally-defined rather than strictly scientifically defined. The complexity and time-consuming aspects of the extraction procedures are also a limitation, which is why it is difficult to compare the results from different laboratories.

The BCR procedure

In 1987, significant changes took place in sequential extraction when the European Commission launched a program within the framework of BCR aimed at harmonizing extraction procedures. In 1993 a standardized three-step SEP (BCR[®] SEP) was proposed (Sutherland, 2010; Ure et al., 1993). In this BCR[®] SEP, metals in the soil are divided into three major fractions: acid extractable, reducible, and oxidizable. The BCR[®] extraction procedure is as follows.

- Step 1. Acetic acid (40 mL 0.11 M) is added to 1 g of soil in a 100 mL centrifuge tube, shaken end-over-end (30 ± 10 rpm) immediately for 16 h at ambient temperature (overnight). The extract and solid residue are separated by centrifugation, and the supernatant solution decanted and stored at 4°C prior to analysis. The residue is washed with water before the next step (20 mL of distilled water, shaken for 15 min then centrifuged).
- Step 2. Hydroxylamine solution (40 mL, 0.5 M $\text{NH}_2\text{OH}\cdot\text{HCl}$ containing 2.5% by volume 2 M HNO_3) is added to the residue, shaken immediately for 16 h at ambient temperature, and centrifuged, decanted and washed as for step 1.
- Step 3. Peroxide solution (10 mL H_2O_2 8.8 M) is added to the residue, heated to $85 \pm 2^\circ\text{C}$ in a water bath and digested for 1 h with occasional manual shaking. The volume is allowed to reduce to <3 mL and a further aliquot of 10 mL H_2O_2 is added and the digestion repeated for 1 h at $85 \pm 2^\circ\text{C}$, and the volume again allowed to reduce to a few mL, then cooled. Finally 50 mL of 1 M

Fig. 2 The modified BCR sequential extraction scheme used for operational speciation of metals.

NH_4OAc (pH 2) solution is added to the residue and the suspension immediately shaken for 16 h at ambient temperature (overnight). Solution and residue are separated by centrifugation and decantation as for step 1 (Fig. 2).

The BCR[®] SEP has been widely used over the last decade since its introduction. However, some suggestions for modification have been proposed. One of the proposals is to add a step to determine the residual fraction. It has been suggested that the residual soil of Step 3 should be digested to determine the total metal content in the residual fraction. This allows the total content to be calculated and thus the metal recovery of each step to be calculated. However, the residual fraction is not an official part of the BCR[®] SEP.

The BCR[®] SEP is similar to the Tessier SEP with some differences. There are the same drawbacks for BCR[®] SEP as for the Tessier SEP. The chief difference is in the first fraction. The BCR[®] SEP does not evaluate the exchangeable fraction and carbonate-bound fraction separately, but combines the two into one fraction, that is, the acid extractable fraction, which leads to more ambiguity in the meaning of the BCR[®] fractions than for the Tessier procedure. The other drawback is the lack of determination of the residual fraction, which prevents any calculation of the recovery of each fraction with respect to the total.

The diffusive gradients in thin films (DGT)

The diffusive gradients in thin films is an in situ device for measuring the fluxes of labile components in water, soil and sediments under undisturbed conditions. The DGT technique was pioneered by William Davison and Hao Zhang of Lancaster University, United Kingdom, in 1993 (Davison and Zhang, 1994). The DGT is a kinetic passive sampler for quantifying trace metals (Guan, 2019). It was initially used to evaluate the concentration of metals in water, and was soon extended to sediments and soils. The DGT device usually consists of a filter membrane, a diffusive gel layer, a binding gel layer and a plastic base and cap. The DGT sampler can be either a piston-type (Fig. 3A) or flat-type (Fig. 3B).

When a DGT sampler is installed in soil slurry (wetted soil), the mobile species of metals from the pore water diffuse through the diffusion layer to the binding layer (chelex gel). The continual removal of metals from the soil pore water to the binding gel induces a concentration gradient within the DGT diffusion layer and immediately adjacent to the soil (Guan, 2019). Unlike extracting reagents, DGT evaluates kinetic processes and the dynamic availability of metals in soils. The DGT has been used to determine the bioavailable metals and phosphorus in soils. It is also widely used to study processes in the rhizosphere by simulating the uptake of metals. Research has shown that DGT can be used to predict plant uptake or the bioavailability of pollutants. The diffusive gradients in thin films is also useful for the selective determination of specific species. When DGT incorporates a high-selectivity agent into the binding gel, it preferentially binds the specific species while excluding other species. It is mainly used to measure trace metals in the medium, whereas its application to organic chemicals is limited. When the DGT sampler is incorporated with other binding agents, such as XAD resin (a macroporous resin) or activated charcoal, it can be used to measure trace organic compounds.

Determination of metals in the extracted solutions

The analytical techniques for determining metals have evolved over time. The most common techniques used for the measurement of metals such as Cd, Pb, Cu, Zn, etc. has traditionally been atomic absorption spectrophotometry, including flame atomic absorption spectrophotometer (FAAS) and graphite furnace atomic absorption spectrophotometer (GFAAS). The FAAS is used for the determination of metals with normal solution concentrations, whereas GFAAS is used for the measurement of metals with small

Fig. 3 Simplified setting schematic drawing of a piston-type (A) and a flat-type (B) DGT sampler.

or trace concentration. Atomic fluorescence spectrophotometry is preferred for the determination of the metalloids (As, Hg (mercury), etc.) while cold atomic absorption spectrometry is used to determine Hg.

The ICP-MS was developed more recently than the above instruments. This instrument has remarkable advantages. It can measure several elements in solution simultaneously with good accuracy and cover a wide concentration range. This instrument is rapidly gaining popularity and is gradually replacing the above instruments.

Concluding remarks

It is well accepted that the total content of metals in the soil does not correlate well with the uptake by plants, whereas there is a better correlation with the more easily extractable, so-called bioavailable fractions. Plants absorb only some parts of the fraction of metals in the soil. All the existing extraction methods aim to extract the 'true bioavailable' fraction of the metals in the soil. Unfortunately, this is unattainable because of the complexity of binding forces between the metal ions and the soil components. In addition, the type and species of plant, the growth and nutrient status, root morphology, and environmental conditions (temperature, humidity, wind, etc.) greatly influence the plant uptake of the metals. The soil's supply of metals is not the unique determinant for plant uptake of metals. The extraction methods developed include different extracting reagents and materials under different extracting conditions, static or dynamic, single or sequential extraction. However, it is impossible to extract the real bioavailable metal content in the soil. At best, chemically extractable metal can be a good estimate of the bioavailable content of the metal.

The selection of extracting reagents is the most important factor. The existing extracting reagents are predominantly water, diluted acid, diluted alkali, neutral salts, chelating agents, and surfactants. Water-soluble metals are the fraction that is the most easily absorbed by the plant. However, the water-soluble metals are always at small or trace concentration, and are very sensitive to external conditions (temperature, moisture, wind, growth position of plant, fertilization, agricultural management, etc.). It is not a stable index. Among the extracting solutions of chemical reagents, the diluted solution of neutral salts seems to be the most similar to the soil environment around the roots. The other chemical reagents are too strong to varying degrees to simulate the soil environment around the roots.

The sequential extraction procedures (SEPs) provide useful tools to probe the distribution of metals in a soil. However, the clear distribution of the metals in soil is still difficult to determine because the fractions extracted by the SEPs are operationally defined and do not correspond exactly to the forms suggested by the terms used to describe them. It is probably not realistic to presume that precise fractions can be extracted chemically. The other problems with the SEPs, such as poor selectivity and redistribution, influence the quality of the extraction. There are some suggestions for modification of the Tessier SEP. However, there is still no formal revised version of the Tessier SEP, but the BCR[®] SEP is an improvement on it. The BCR[®] SEP has better reproducibility than the Tessier SEP, partly because certified reference soils have been defined. However, the BCR SEP is still not able to extract the real fractions indicated by their names.

The DGT is essentially a single extraction method but it is quite different from single extractions. It determines dynamically the supply capacity of the soil metal content, and measures the mobile and labile species rather than other inert species of the metals. The DGT shows good predictability for the bioavailability of the metals in the soil.

It should be pointed out that both the conditions of the soil and crop control the uptake, transport of a metal from the soil to the crop, and final accumulation in the edible part. Sometimes, transport of the metal within the crop is more important than the supply capacity of the metal in the soil. The uptake and transport of metals in crops differs from crop to crop, and is influenced by many environmental factors. It is difficult to develop a method that predicts perfectly the accumulation of metals in the soil, especially when a large area (such as a province, a country) is being dealt with.

Abstract

This chapter provides an overview of the relevant chemical features of organic carbon in soil. To this end, the text presents three major, functionally and molecularly discernible categories of organic carbon compounds in soil: (1) Organismic, (2) Xenobiotic and (3) Pyrogenic—thermally altered carbon forms. A brief appraisal of the functional relevance of these carbon forms is provided. The definition of “Soil organic matter” continues to evolve, and it is increasingly conceptualized as a dynamic system component rather than as a particular molecular phase. Increasing amounts of organic compounds have been added to the environment over the past 60 years to which natural systems are not adapted.

Key points

- The definition of “Soil organic matter” keeps evolving.
- Soil organic matter is increasingly conceptualized as a dynamic system component rather than as a certain molecular phase.
- The past 60 years have added increasing amounts of organic compounds to which natural systems are not adapted.
- The macro- and micro-scopically structureless organic mass of the soil, also called Humus, encompasses both floral (i.e. plant derived) and microbial necromass at some degree of degradation.

Introduction

To describe the composition of soil organic matter (SOM), it is necessary to define the term. This is not as straightforward a task as one would initially think. To understand the underlying conceptual challenge better, it is useful first to examine the basic convention used to distinguish between major forms of carbon that may occur in soils—the distinction between inorganic C and organic C (Fig. 1).

Organic and inorganic carbon

Fig. 1 shows the long-standing practice to separate the so called “organic carbon” from other carbon containing compounds. The notion that there is such a thing as “organic carbon” dates back to the early days of chemistry as a scientific discipline. During those days, early researchers wanted to recognize such carbon containing materials that were exclusively produced by organisms. But when Wöhler (1828) synthesized the supposedly organic compound Urea [$\text{CO}(\text{NH}_2)_2$] in his laboratory using inorganic precursors, he coincidentally eliminated the basic premise “formed by a living organism” underlying the production and recognition of organic substances.

Accordingly, the separation of soil carbon into organic and inorganic forms (Fig. 1) is a convention from the past, involving numerous inconsistencies. For instance, carbonate minerals and gaseous carbon dioxide are not typically considered “organic compounds” despite the fact that they are more often than not produced by living organisms. Note also that any analytical procedure that measures total carbon in a soil sample will always include carbon from both inorganic and organic forms.

Soil organic matter (SOM) and humus

Having pointed out the problematic nature of distinguishing between organic and inorganic carbon, we find that similar issues must be confronted when attempting to define “soil organic matter”. Here, the problem lies in the fact that scientists realized early

Carbon in soil

Organic carbon	Inorganic carbon
<i>Historic emphasis:</i> "compounds produced by living organisms". <i>Modern emphasis:</i> "a chemical compound in which one or more atoms of carbon are covalently linked to a hydrogen or to atoms of other elements"	Varying conventions arbitrarily exclude CO_2, carbonates (CO_3^{2-}), carbides (CaC_2), cyanides (CN^-) and others from being considered as organic compounds
1. Organismic: - C in living organisms as well as - C in naturally occurring organic residues at various stages of decay, - soluble and insoluble organic metabolites, - involving all forms of biomolecules such as carbohydrates, lignin, proteins, lipids, low molecular weight organic acids, methane and other volatiles	4. Fully oxidized, highly mobile carbon in the - gas phase / soil air, CO_2; and in the - aqueous phase / soil solution, CO_3^{2-}; HCO_3^-; H_2CO_3; also known as dissolved inorganic carbon (DIC)
2. Xenobiotic: anthropogenic origin, not produced by natural systems, can be separated into - monomeric (often halogenated, such as organic pesticides, fungicides, herbicides, fire fighting foams) and - polymeric species (compounds of high molecular mass, often micro-particulate, anthropogenic origin, such as industrial polymers (plastics and microplastics))	5. Carbonate minerals (Calcite, Dolomite, Siderite, Aragonite etc.) either - formed in situ as secondary precipitate (calcrete, caliche) or - inherited from biogenic sedimentary regolith
3. Pyrogenic carbon: organic matter with a history of thermal alteration in the absence of oxygen (= pyrolysis); can be tentatively divided into materials resulting from	
- low temperature pyrolysis (creating volatiles and viscous, tar like compounds)	- high temperature pyrolysis (creating mineral-resembling carbon microcrystallites)

Fig. 1 Organic versus inorganic forms of carbon in soil. Note that, depending on pyrolysis temperature, thermally altered carbon (Box # 3) can exhibit both 'organic' and 'mineral' features, such as considerable crystallinity. Bold face indicates the carbon forms considered to be part of the soil organic matter continuum: (1) Organismic, (2) Xenobiotic, and (3) Thermally altered, pyrogenic carbon.

on that there are forms of organic matter in soil that differ significantly in functionality. Living organisms, for instance, are composed of organic compounds, however, they contribute in other ways than their residues (which are also organic compounds) to soil functionality, especially when those residues have undergone extended oxidation and fragmentation and are then called 'humus'.

As science progressed from the days when humus was considered the most important fraction of the organic matter in soil, definitions of SOM have changed their emphasis. This change involved two major aspects. There has been a progressive abandonment of the historic trend to equate SOM with just the fraction that satisfies the definition of humus towards an all-inclusive-type view (see "Static view" in Table 1). Over the same time frame, and reflecting the difficulty to constrain SOM as a chemical category, there is now a tendency to define SOM no longer as a chemical substance or mixture thereof, but as a continuous flow of organic carbon compounds through the soil (see "Dynamic View" in Table 1). Note that the static and dynamic approaches illustrated in Table 1 are compatible and not mutually exclusive: the complex and varied mixture of Weil and Brady (2016) can be highly dynamic as proposed by Hedges et al. (2000) and Janzen (2006, 2015).

Table 1 A compilation of relatively recent definitions of “SOM”.

<i>Static, ‘chemical’ view. SOM is:</i>		<i>Dynamic, ‘functional’ view. SOM is:</i>	
Trumbore (1997)	“The natural, nonliving component of organic matter in soil”	Hedges et al. (2000)	“A thermodynamic anomaly atop a free energy precipice that drops off on all sides to dispersed, stable ingredients such as carbon dioxide, water, nitrate and phosphate”
		Janzen (2006)	“A relentless flow of C atoms, through a myriad of streams—some fast, some slow—wending their way through the ecosystem, driving biotic processes along the way”
Baldock and Broos (2011)	“The sum of all naturally derived organic materials”	Janzen (2015)	“A dynamic hub in the energy cycles of our ecosystems”
Weil and Brady (2016)	“A complex and varied mixture of organic substances”		

Definitions either attempt to constrain the chemical characteristics of SOM (‘chemical’ view) or to emphasize its highly dynamic nature (‘functional’ view).

An important corollary of these two trends to categorize organic matter is their incompatibility with the view that the ideal state of organic matter in soil should be that of a ‘stable’, long lasting type of material. This is a view that is deeply ingrained in the scientific community and that has historically been the basis of land management recommendations for practitioners.

As science progresses, more challenges and complications have added to the dilemma of constraining the meaning of the term SOM. At issue here are the growing volumes of non-natural organic compounds deposited to soils worldwide. Examples are organic agrochemicals (pesticides), organic industrial contaminants (such as oil spills or fluorinated firefighting foams) and, increasingly recognized, the industrial polymers commonly called plastics. Once these non-natural compounds get into the soil they become substrates, catalysts and reactants for organisms and must be considered as having the potential to interfere with soil functions. Omitting xenobiotic compounds as part of SOM may not be the best way to address the issue.

We realize that for many in the scientific community, there is a conceptual difference between the totality of organic materials that can be found in soil (“organic matter in soil”, including anything that satisfies the definition of an organic compound, such as living organisms, charcoal, microplastics and even xenobiotics) and the subset of these materials that is “the macro- and microscopically structureless organic mass of the soil” (Pauli, 1961) or humus. It is impossible to ignore or evade the widespread informal understanding among practitioners and scientists that the label “SOM” should refer primarily to the insoluble amorphous organic residues (traditionally: humus, also: necromass when of microbial origin) that result from the processing of organic debris by the decomposer community. The combined humus and necromass subfraction often constitutes the largest proportion by mass of total soil carbon and closely relates to soil fertility and other vital soil functions, making it a worthy object of investigation. Fig. 2 illustrates the material categories that produce necromass and humus, including the organisms that actively process organic residues, any molecular fragments that have sufficient polarity to be dissolved or are small enough to be suspended in the soil solution, and organismic detritus as the ultimate source of organic inputs.

Organismic carbon in soil

The chemistry of bulk plant biomass inputs into soils has been comprehensively discussed by Oades (1989) and Kögel-Knabner (2002, 2017) and includes a wide range of compounds such as cellulose, hemicellulose, lignin, protein, DNA, RNA, lipids, waxes, resins and an unlimited number of composites of the above (Fig. 2).

A major insight from these publications is that about 80% of dry plant biomass is macromolecular and or composed of nonpolar organic compounds, and for that reason, is initially not soluble in water (neither plants nor animals dissolve in the rain). Although rarely fully saturated even in humid climates, soils are fundamentally aqueous systems, meaning that their functionality relies on the presence of water as a solvent and means of transport. Accordingly, before further decomposition, organismic debris needs to undergo pretreatment to increase water solubility, and thus mobility, in the soil system. Such pretreatment is also needed to reduce biomacromolecular compounds to molecular sizes small enough for passage through microbial cell walls, because final conversion of biomolecular precursor fragments to the highly oxidized end products CO₂ (carbon dioxide) and HCO₃⁻ (bicarbonate) occurs inside the cells of decomposer organisms. This pretreatment involves incremental breakdown of biomacromolecules by microbial exoenzymes, decreasing the size of primary plant inputs, increasing the polarity of the hydrolyzed or oxidized intermediates, and thus increasing organic matter (OM) solubility in the polar solvent H₂O.

It is necessary here to recognize a process that was not well understood in the early days of SOM research. That is, the carbon, nutrients and energy supplied by primary plant inputs will, after processing and assimilation by decomposer organisms, contribute to the de novo synthesis of bacterial and fungal biomass, primarily generating proteins and cell wall lipids. The efficiency (microbial carbon use efficiency, CUE) at which this occurs appears to be a function of the nominal oxidation state of the carbon in a given compound, moderated by soil temperature regime and nutrient availability.

Fig. 2 Five categories of organismic inputs of carbon to the soil. Inputs differ in chemical composition and structure depending on microbial vs plant origin, and whether exudates originate from living organisms or from decomposition of dead organisms. Regardless of organismic input, these materials can eventually be transformed to amorphous, dispersed, or dissolved organic compounds in soil. Modified after Kögel-Knabner I (2017) The macromolecular organic composition of plant and microbial residues as inputs to soil organic matter: Fourteen years on. *Soil Biology & Biochemistry* 105: A3–A8, with permission.

The implications of these transformations for the chemical characteristics of SOM can be visualized by following functional group abundances over the duration of a decomposition experiment (Baldock et al., 2004) (Fig. 3).

As plant residues decay, the carbon that is not respired is synthesized into microbial biomass, leading to an increase over time in proteinaceous and lipid-like materials within the pool of residual materials. Fig. 3 shows that as carbohydrates (O-alkyl carbons) are being consumed, the abundance of carboxylic and amide groups increase, together with the relative proportion of alkyl C

Fig. 3 Chemical alterations (shifts in functional group abundances) of maize (*Zea mays* L.) residue buried at 15-cm depth under deciduous forest over the duration of a 19-month decomposition experiment. Carboxylic groups are found in the 165–220 ppm region; aromatic compounds are between 110 and 165 ppm; carbohydrates range from 60 to 110 and lipids are between 0 and 60 ppm. Data from Baldock JA, Masiello CA, Gelinas Y and Hedges JI (2004) Cycling and composition of organic matter in terrestrial and marine ecosystems. *Marine Chemistry* **92**: 39–64.

representing lipid-like materials. Fig. 3 illustrates that a soil at steady state with regard to the balance between organic matter input and output is similar to the digestive tract of an animal in that it

- constitutes a flow-through system that will
- contain variable proportions of organic input materials at various stages of depolymerization and oxidation, and
- the materials synthesized by the soil microbiome.

Quantitative assessments of the relative contributions of microbially derived materials to SOM have recently been given by two research groups, using comparable methodologies (Angst et al., 2021; Liang et al., 2019; Table 1).

Table 1 suggests that bulk soils under agricultural use have slightly higher proportions of microbial necromass compared with micro- and macro-aggregates from agricultural soils. Two considerations may help in understanding the discrepancy: the database for agricultural bulk soils is significantly larger than that for soil fractions (64 versus 14; Table 2), and the process of separating the physical fractions usually involves considerable exposure to the aqueous phase through wet sieving, flotation and similar procedures, thereby facilitating the loss of soluble compounds. The latter process would lead to a relative enrichment of insoluble plant debris.

Fundamentally, both studies corroborate the notion that the macro- and micro-scopically structureless organic mass of the soil is a mixture of plant debris in various stages of decay and microbial necromass'. The organic matter from grassland soils is particularly rich in microbial contributions while that from forest soils has greater proportions of plant debris.

Residence time of carbon in soil as a function of chemical composition. The appreciation of soil as a flow-through system and of SOM as a relentless flow of carbon means that there is a need to explain why small proportions of organic matter can reside in the

Table 2 Trends in relative contribution of microbial necromass to soil organic matter.

Land use/soil subfraction	# of observations	Microbial necromass %	Bacterial %	Fungal %	Plant residue %	Source
Grassland (0–25 cm)	31	61.8	17.6 ± 1.6	44.2 ± 2.5	38.2	Liang et al. (2019)
Agriculture (Ag) (0–25 cm)	64	55.6	15.5 ± 1.0	40.1 ± 1.8	44.4	Liang et al. (2019)
Micro-aggregates (53–250 µm)	14 (all Ag systems)	49.7	9.1 ± 1.5	40.6 ± 6.5	50.3	Angst et al. (2021)
Macro-aggregates (250–2000 µm)	14 (all Ag systems)	47.2	8.6 ± 1.4	38.6 ± 6.4	52.8	Angst et al. (2021)
Mineral associated	23 (16 Ag, 5 Forest, 2 Grassland)	38.6	15.3 ± 1.6	23.3 ± 4.2	61.4	Angst et al. (2021)
Forest (0–25 cm)	27	32.4	8.7 ± 1.5	23.9 ± 2.4	67.4	Liang et al. (2019)

Data from Angst G, Mueller KE, Nierop KGJ and Simpson MJ (2021) Plant- or microbial-derived? A review on the molecular composition of stabilized soil organic matter. *Soil Biology and Biochemistry* **156**: 108189.; Liang C, Amelung W, Lehmann J and Kastner M (2019) Quantitative assessment of microbial necromass contribution to soil organic matter. *Global Change Biology* **25**: 3578–3590.

soil for millennia. Chemical explanations have been sought to explain these very long residence times. As soils evolve over time from mineral parent materials, their organic matter content typically increases. It is tempting to interpret this observation as an accumulation of such organic phases that have ‘resisted’ decomposition and are thus ‘stable’. This view is supported by numerous decomposition experiments that show certain organic compounds tend to decompose more slowly than others. However, as soils mature, their organic matter concentration always equilibrates (except for peat bogs (histosols) where the biomass produced is preserved through the absence of oxygen). If inherently stable organic compounds were produced, organic matter contents (= the thickness of A horizons) should never equilibrate, they would be expected to increase infinitely, much as pedogenesis can create B horizons of almost unlimited thickness. As early as 1981, this insight led [Jenkinson \(1981\)](#) to postulate that “in the long run, no fraction of organic matter in plants and animals can withstand decomposition to carbon dioxide and water. If this were not so, any completely resistant fraction would by now cover the surface of the earth”.

In contrast to this fundamental consideration (all natural organic matter will eventually decompose unless it is effectively isolated from decomposition processes), the notion that molecular complexity and degree of polymerization should slow down decomposition has received strong support from the work of Martin and coworkers. These scientists introduced ^{14}C into the molecular structure of phenolic acids and artificially prepared phenolic polymers [Haider and Martin \(1975\)](#), allowing them to identify the molecular origin of the carbon in the $^{14}\text{CO}_2$ evolved during decomposition of these molecules and demonstrating that assembling monomers into polymeric structures slowed the decomposition of organic carbon in 12-week incubation experiments. As a result, macromolecularity has long been considered one of the major factors determining the persistence of organic C in geosystems.

Together with earlier suggestions that so-called humic substances have macromolecular structure analogous to seemingly indestructible industrial polymers, these experiments contributed significantly to the view that the chemistry of an organic substrate determines its likelihood of decomposition. Early soil carbon models (Roth C, Century) were based on this premise and assigned intrinsic turnover times to certain molecular categories such as cellulose and lignin.

Residence time of carbon in soil as a function of system architecture, resulting logistics and decomposer specialization. As shown above, the phenomenon of slow decomposition has long been related to the compound in question (such as lignocellulose) being able to ‘resist’ decomposition. However, the notion of an organic compound resisting a chemical reaction is physicochemically incorrect and diverts our attention from the true nature of the underlying mechanisms. Ultimately, decomposition is a sequence of chemical reactions. In chemistry, reactions take place when there is motive and opportunity: the ‘energetic’ requirements for a specific reaction to occur need to be satisfied. The Gibbs free energy, ΔG , of the reaction must be negative, and resource requirements must be met, such as the availability of catalytic tools (enzymes), electron acceptors (O_2), a suitable solvent (H_2O), etc. The reactants in a chemical reaction never ‘resist’; either the requirements for a reaction to proceed are satisfied or they are not. This insight necessarily directs our focus towards the logistic status of a system when we try to rationalize why a certain organic compound is left undecomposed ([Ekschmitt et al., 2008](#)): Is the compound accessible to the decomposer community? Are there decomposers in the system with the appropriate catabolic toolbox? Is there enough oxygen? Is the system too wet or too dry? Are the co-metabolites needed to facilitate the reaction available?

Once the energy and logistic requirements for chemical reactions are in place, decomposition can and will proceed, as demonstrated by [Klotzbuecher et al. \(2011\)](#) for lignin decomposition. Plants have evolved to select and utilize composite molecular compounds (such as cutin and suberin) that require sophisticated logistics to be processed, such that the decomposer community tends to prioritize substrates with easier logistics (such as carbohydrates). Parallel to this, evolution also continues to incentivize decomposer adaptations, resulting in organisms such as termites (that enlist endosymbiotic microorganisms to deal with woody substrates in hours) and white rot fungi (elaborate ‘chemical factories’ able to synthesize both complex enzymes and source the required molecular supplies through their hyphal network). For these reasons, the chemistry of a substrate will influence its turnover dynamics. However, the underlying causality is a matter of resource availability and not a matter of ‘resistance’.

Although organic matter can reside in the soil for millennia, it does not do so because its chemical composition renders it inherently resistant to decomposition. As we strive to understand why a compound or fraction of organic matter decomposes more slowly than others, we need to resist the temptation to classify substrates as inherently labile or inherently stable. A compound such as lignin or even biochar is not left behind because it is ‘recalcitrant’, but where the complicated logistics for its decomposition are not in place (no termites, no white rot fungi, lack of oxygen, lack of co-metabolites, etc.).

Carbon in soil and the humic substances paradigm. The decomposition process produces a cascade of intermediate products with specific properties (structurally amorphous, water insoluble, enriched in ionizable carboxylic groups.) that

- a) visibly distinguish them from other soil constituents and
- b) render those decomposition intermediates highly relevant for the functioning of soils ([Fig. 4](#)).

Examples of such soil functions are the cation exchange capacity contributed by organic matter in advanced decomposition stages and the facilitation of aggregation processes that eventually determine the volume and shape of the pore space needed for life processes within the soil.

The so-called “humic substances paradigm” ([Wershaw, 2000](#)) posits that soil humus is composed of the end products of synthetic reactions that alter the structure of plant degradation products in a way that provides these newly synthesized materials with unique properties that are distinct from non-humified organic matter. At its outset, the humic substances paradigm ([Fig. 5](#)) was conceived to reconcile apparent chemical properties (high molecular mass, large abundance of aromatic moieties and resulting inherent recalcitrance) in a way that would explain the observed dark coloration, slow turnover and resulting old radiocarbon ages of the amorphous, water insoluble organic residues typical for SOM ([Fig. 2](#), bottom left).

Fig. 4 Conversion of plant debris with clearly recognizable macroscopic plant structure (soil surface, far left) into a water-insoluble, seemingly amorphous residue (far right, 40-cm depth). Image taken by the author, showing 5–10 cm depth increments from the surface of a Haplorthod at the Oregon Coast. Note the color change associated with the transformation of brownish plant debris (far left) to amorphous humus (black, far right).

Fig. 5 (A) Trajectory of decomposing organic matter according to the humic substances paradigm, involving initial breakdown followed by subsequent secondary synthesis of decomposition products into intermediate humic and fulvic substances. Approximate NOSC values derived from average elemental compositions of alkali extracted humic substances ($n = 26, 214$ and 410 for humin, fulvic acid and humic acid, respectively) using data from Table 4.3 (all sources) in [Essington \(2015\)](#). (B) Trajectory of decomposing organic matter according to the Continuum Model ([Lehmann and Kleber, 2015](#)), involving progressive deconstruction of organic biomacromolecules to fully oxidized carbon (CO₂; HCO₃⁻).

Evidence has accumulated that the macro- and micro-scopically structureless organic mass of the soil is rarely macromolecular, it is not always highly aromatic, and it may decompose readily if given the opportunity to do so. Together with the lack of a thermodynamic rationale for decomposer organisms to synthesize compounds that deliberately lack any obvious metabolic purpose as proposed by the humic substances paradigm ([Fig. 5A](#)), these findings led to suggestions that this paradigm is an outdated chemical model for SOM. Rather, the evidence available to date suggests that SOM is more accurately represented as a continuum of organic compounds in various stages of decay ([Lehmann and Kleber, 2015](#); [Trumbore, 1997](#)) experiencing progressive oxidation and reduction in molecular size ([Fig. 5B](#)).

Xenobiotic organic compounds

Xenobiotic organic compounds are organic chemicals that are foreign (Greek *xenos* = stranger, guest) to natural living systems. Modern society relies heavily on thousands of chemical compounds that did not exist before the industrial revolution some 200 years ago. Because life was not exposed to these compounds during evolutionary processes of the past, it has had no opportunity to adapt to their presence. This means that the organisms in a natural system have, apart from some rare metabolic coincidence, no adaptations that would allow them to catabolize these compounds or to exclude them deliberately from their metabolism. This can result in toxic effects and to an unwanted accumulation in soil environments and in the organisms inhabiting the soil. Xenobiotic organic compounds can loosely be subdivided into monomeric and polymeric categories.

Monomeric xenobiotics. Monomeric xenobiotics are either deliberately applied to soils, such as agricultural pesticides, or end up in the soil as a consequence of their tolerated or accidental release into the environment, such as veterinary antibiotics or *per*- and poly-fluoroalkyl substances. Quantitatively, these additions may, at first sight, seem insignificant. In 2018, the world average pesticide use per area of cropland was 2.63 kg ha⁻¹ ([Raffa and Chiampo, 2021](#)), which would be equivalent to 0.00263% of the

100,000 kg of organic matter in the top 25 cm of an agricultural field containing 4% of organic matter at a bulk density of 1.0 kg L⁻¹. However, a recent analysis of pesticide effects on soil invertebrates involving 284 different active pesticide ingredients and 275 unique invertebrate species found that 70.5% of properties tested showed negative effects, whereas only 1.4% and 28.1% showed positive or no significant effects, respectively (Gunstone et al., 2021). Attempts to characterize the influence of pesticides on microbial community composition and soil enzyme production are less conclusive (Wolejko et al., 2020). There is some evidence that microbial communities may respond more strongly to the application of different types of natural organic substrates than to the application of a given herbicide (Carpio et al., 2020). More research is needed to clarify pesticide effects on microbial metabolic performance as well as on microbial community composition. At present, however, it appears that soil invertebrates are under greater pressure from pesticide applications than are the more diverse and more adaptable microbial communities.

Apart from concerns for the general functionality of soil organisms, xenobiotics that are introduced in more confined areas warrant attention from a human health standpoint. Manure or sludge applications to the soil may create source zones for veterinary antibiotics (Kemper, 2008; Tasho and Cho, 2016), enabling eventual transfer to human food and water supply systems. Another example of the creation of soil source zones of xenobiotic compounds with potentially harmful effects on human health are the training areas for fire fighters around military bases, airports and other industrial locations (Hu et al., 2016). Poly- and per-fluoroalkyl substances (PFASs) are present in aqueous film-forming foam (AFFF) formulations used to suppress fires caused by aviation fuel and similar nonpolar liquids. These fluorinated compounds are designed to accumulate at the interface between burning fuel and overlying air, thereby sealing the burning liquid off from atmospheric oxygen supply. The PFAS can be initially retained by soil matrices (Barzen-Hanson et al., 2017; Nickerson et al., 2021) and are considered to degrade at very slow rates (Kwiatkowski et al., 2020), however lateral export with groundwater flow of PFAS and their transformation products has been documented (Adamson et al., 2020) and may affect aquifers needed for human water supply.

Polymeric xenobiotics (plastics and microplastics). While 4.1 mt of agricultural pesticides were applied globally in 2015 (Maggi et al., 2019), the global production of industrial organic polymers, also known as plastics (microplastics if smaller than 5 µm), was two orders of magnitude higher at 367 mt in 2020 (Rouch, 2021). Estimates of global emissions of plastic waste to rivers, lakes, and oceans range from 9 to 23 mt per year, with a similar amount emitted into the terrestrial environment, from 13 to 25 mt per year as of 2016 (Borrelle et al., 2020; Lau et al., 2020). According to MacLeod et al. (2021), these rates of emission estimated in 2016 will double by 2025. These authors also suggest that the amount of plastic in the world's agricultural soil may be larger than on the ocean's surface.

Bläsing and Amelung, 2018 identified plastic litter, road runoff (including tire wear particles), and atmospheric deposition of micro- and nano-plastic particles as sources of plastic pollution to urban and rural soils. Other input pathways to soils are plastic mulching with polyethylene films and so-called 'biodegradable' plastic films, compost, and sludge-derived biosolids, as well as polymeric stabilizers against soil erosion. Quantitative estimates for plastic fractions in soils reach up to 0.1% of soil organic carbon (Bläsing and Amelung, 2018) and are at least two orders of magnitude greater than estimates for pesticide applications (Raffa and Chiampo, 2021).

Plastic concentrations in soil are expected to increase because of these ongoing sources of emission combined with extremely slow rates of degradation (MacLeod et al., 2021). Although plastics undergo various fragmentation and disintegration processes, Bläsing and Amelung, 2018 estimate that less than 1% of the mass of conventional plastic will leave the soil on annual time scales, making plastic pollution of soils a poorly reversible phenomenon.

Unfortunately, plastics are not inert admixtures to the soil system. Bandyopadhyay et al. (2018) report long-term changes in soil properties, such as water holding capacity, microbial activity and diversity, nutrient availability, and soil structure associated with increased loads of plastic.

Other implications of plastic accumulation in soils include effects on plant performance and plant diversity and potentially irreversible soil degradation (Steinmetz et al., 2016). Observations from studies in aquatic systems suggest that processes of nitrogen and phosphorus cycling can be affected by microplastics.

Xenobiotic compound summary. For about 60 years, both monomeric and polymeric xenobiotic compounds have been added to soils in ever increasing quantities, and evidence for their role as global stressors in terrestrial ecosystems is mounting. Microplastics <700 nm have now even been found in human blood (Leslie et al., 2022), adding urgency to the need to include these materials in modern concepts of SOM, despite the fact that their quantitative contribution may seem small.

Thermally altered C

Before the advent of the first computer-based models for the turnover of SOM, pyrogenic carbon (carbon compounds formed from organic matter by pyrolysis, i.e. through heating in the absence of oxygen), was not considered a functionally relevant part of SOM. However, when computer models were developed, it was found that they needed to include a supposedly 'inert' conceptual organic matter pool. Inert organic matter is defined as a fraction of SOM that is biologically unreactive and has an equivalent radiocarbon age of more than 50,000 years. The inert organic matter pool is a device to allow the model to represent short-term changes in SOM brought about by changes in land management, and at the same time to account for the great radiocarbon ages measured in surface soils collected before thermonuclear tests. Of all the known forms of carbon, charcoal was seen as one of the most likely candidate materials representing this pool.

Almost parallel to the development of the first carbon turnover models was a report (Seiler and Crutzen, 1980) on the substantial sink of atmospheric CO₂ by the formation of black carbon in vegetation fires. The authors argued that a relatively

unknown (at that time) fraction of the vegetation exposed to fire is converted to an extremely long-lived form of carbon. Because the resulting pyrogenic or 'black' carbon was considered 'refractory', it was seen as a potential explanation for the so-called missing carbon sink, i.e. the discrepancy between the annual release of carbon into the atmosphere from fossil fuel combustion and the actual, observed uptake of carbon by the atmosphere. Scientists are now more reserved about this interpretation, but 30 years ago, the scientific community connected the dots between (i) model requirements for an 'inert' carbon pool, and (ii) recognition of significant black carbon inputs to terrestrial systems, and began to investigate the abundance of pyrogenic carbon in soils more closely.

Abundance of pyrogenic carbon in soil. The first quantitative report of pyrogenic carbon in soils came from Australia, a continent dominated by fire-adapted ecosystems. Skjemstad et al. (1996) estimated that 30% of soil carbon was pyrolytic in the soils investigated. This number attracted wide attention, and numerous studies into other ecosystems followed. It soon became clear that admixtures of pyrogenic carbon to soils are globally ubiquitous, reaching particularly high values in boreal forests and in grassland soils. On a global scale, Reisser et al. (2016) found that pyrogenic carbon contributed on average 13.7% of the soil organic carbon, effectively making it one of the largest groups of chemically distinct carbon compounds in SOM. Reisser et al. (2016) also noted that soil properties and climate variables were statistically correlated with the abundance of pyrogenic carbon, suggesting that factors such as clay content and MAT/MAP (mean annual temperature/mean annual precipitation) were instrumental in the retention of pyrogenic carbon.

Chemistry of pyrogenic carbon. The chemical composition of pyrogenic carbon is a function of (i) the properties of the organic precursor material (wood, grass, fossil fuel etc.) and of (ii) pyrolysis conditions, i.e., the duration and intensity of the exposure to heat. At low temperatures, plant biomass is mainly dehydrated and remains otherwise unaltered. As charring intensity increases, organic macromolecules, e.g., cellulose, lignin and hemicellulose, are lost, and isolated aromatic rings begin to form. Eventually, recognizable biopolymers are lost and isolated aromatic molecules with 2 and 3 rings are formed. When temperature increases further, small and somewhat 'defective' sheets of condensed aromatic rings stack up to form so called turbostratic crystallites. These are small three-dimensional structures that consist of 3 to 5 stacked C sheets with a vertical height of 1–2 nm and a lateral extension of 2–5 nm. These dimensions depend on many factors such as type of organic precursor material (for instance, wood versus grass), peak heating temperature and mineral admixtures. When all amorphous organic C has either been volatilized or converted into aromatic rings, the material is designated as 'carbonized'. Pyrogenic carbon formed in natural environments will not typically fall into this latter category as it either requires prolonged exposure to pyrolysis conditions or heating temperatures in excess of about 700 °C, conditions that are rarely or only briefly met in vegetation fires. However, dependence of the molecular properties of pyrogenic carbon on pyrolysis conditions means that pyrolytic carbon can exhibit a predominance of 'organic' carbon forms when resulting from low intensity pyrolysis, or show decidedly 'mineral' or 'inorganic' features when assembled into graphite-like crystallites able to diffract X-ray radiation. This raises the interesting question of whether highly crystalline chars should still be considered part of the organic carbon pool in soil, or as part of the inorganic mineral matrix (Fig. 1).

With pyrogenic carbon presenting in many diverse molecular forms, identification and quantification of thermally altered carbon in soil remains an analytical challenge that has prompted numerous efforts to standardize and optimize the analytical portfolio.

Impact of pyrogenic carbon on soil functions. Pyrogenic carbon is by no means a chemically homogeneous material. It is no surprise that soil and plant responses to additions of pyrogenic carbon can be negative, positive, or neutral (Joseph et al., 2021). A vibrant research community is presently studying the effects of deliberate additions of well characterized varieties of pyrogenic carbon (so called biochar) to soils. These efforts are expected to contribute to a mechanistic, and potentially generalizable, understanding of the ecological consequences of the contribution of different forms of pyrolytic carbon to soil functionality.

Conclusion and outlook

Humankind has known for millennia that the organic phase is vital for the functioning of soil. Prior to the industrial revolution, a focus on "the macro- and microscopically structureless organic mass of the soil" or humus was understandable and justified as an expression of the recognition of the particular importance of these materials. With the onset of the industrial age, humankind has deliberately applied or tolerated deposition of increasing amounts of xenobiotic organic compounds to which neither plants nor decomposer communities were adapted to. Thermally altered, 'black' carbon was always part of the organic phase in soil, but its ubiquity and quantitative significance has only become known over the past 40 years. In the light of these developments, our concepts of the chemical composition of soil organic matter need to be reevaluated and modernized. A new view is emerging that SOM could be represented more accurately as a continuum of organic compounds derived from both punctuated and continuous processes, natural and anthropogenic sources, and in various stages of decay.

The stage for future research on SOM is set by an acknowledgement of the three major environmental aspects of Global Change: Soil Degradation, Loss of Biodiversity and Climate Change. So far, only Climate Change has received due attention in the media and by the public. This makes it difficult for the scientist to find the resources necessary to develop countermeasures against soil degradation and loss of biodiversity, it also hinders coordinated and timely action by legislators. For this reason, public initiatives such as the Soil Health movement warrant attention and active support from the scientific community.

Abstract

Physical fractionation methods enable the separation of soil organic matter fractions that differ in their function, formation pathways, and persistence in soils. Several different physical fractionation methods have been developed to separate different components of soil organic matter by either particle size, particle density, or a combination of these characteristics. Here we summarize these techniques, providing first a conceptual framework for the fractions that are isolatable, and then describing the variety of methods that have been used by researchers to differentiate various fractions.

Key points

- The function and formation of soil organic matter can be better understood by separating it into fractions defined by their physicochemical characteristics.
- Depending on the goals of the researcher, several different fractions can be isolated by separating particles based on size, density, or a combination of the two properties.
- The method of dispersion as well as the dispersing solution used present important considerations for researchers using these methodologies.

Introduction

Soil organic matter (SOM) is a key renewable resource, providing several ecosystem services such as the regulation of nutrient cycling, soil water storage, and carbon sequestration. Soil organic matter is largely composed of diverse, relatively simple molecular compounds that are present in the soil solution, attached to mineral particles, or contained within fragmented organic residues (von Lützow et al., 2007). Over the last 40 years, continued advancements in SOM research have led to an increasing acceptance that to understand best the function, formation, and persistence of SOM, different components must be isolated and examined as critical parts of a greater whole (Cambardella and Elliott, 1992; Christensen, 2001; Lavallee et al., 2020; Lehmann and Kleber, 2015; Sollins et al., 1984). Several methods of separating SOM fractions have been developed, such as the now dismissed use of strong alkaline extractions to isolate organic molecules (Stevenson, 1994), or laboratory incubations that aim to determine turnover times of

different SOM constituents (Paul et al., 1999). In this chapter, we focus our discussion on methods of isolating organic matter fractions by physical means.

Physical fractionation methods enable the isolation of SOM fractions that are less heterogeneous in their turnover time, formation processes, and/or chemical make-up than the bulk SOM. In contrast to other methods of SOM separation, physical fractionation methods reduce the potential for procedural artifacts or modification of the chemical composition of the final samples, and produce samples fit for further analysis (e.g., elemental and isotopic composition, hydrogen pyrolysis, etc.). Most importantly, these physical methods have been developed to separate SOM into fractions based on inherent physiochemical properties, which allows increased insight into the mechanisms of SOM formation, stabilization, and persistence of the different components.

A distinguishing feature of the current paradigm of SOM research has been an inquiry model that exists downstream from the methodology at the researcher's disposal. That is to say, the questions asked are often directly informed by the techniques for separating constituent fractions, rather than fractionation approaches dictated by the differences that exist in the function, formation, and persistence of the substances that comprise the organic component of the soil. The fractions we discuss in this chapter are by nature operationally defined, and the operational definitions will vary given the dogma of a given laboratory, institution, or researcher. While the wealth of high-quality research under this paradigm has brought about a deep understanding of SOM dynamics, the foundation is now strong enough such that we have the opportunity to craft questions using an inductive reasoning framework and to use methods that are informed by the scope of our inquiry, rather than inform it. Here we provide an overview of the different functional components of SOM, the relevance to research studies, and the ways in which researchers can go about separating these components. Our intention is to provide a resource for researchers to develop an understanding of the most typical products of physical fractionation schemes, the information they can provide, and the methods by which they can be isolated such that researchers can make informed decisions concerning the techniques they employ.

Conceptual framework

The molecules within a given organic residue or exudate entering the soil have a variety of potential fates once they begin to decompose and become part of the SOM pool. The secretion of specialized extracellular enzymes by soil microbial communities transforms insoluble molecules such as cellulose, hemicellulose, lignin, suberin and pectin contained within the structural components of plant tissue into low molecular weight compounds by a repeated process of colonization and depolymerization. In contrast, exudates and soluble compounds within residue such as organic acids, amino acids, and sugars, are readily leached from the residue and enter the soil solution directly. Low molecular weight compounds can be assimilated into the microbial biomass or respired by soil microbes, but may also bypass microbial interactions altogether and associate with mineral surfaces, often creating strong and long lasting bonds (Liang et al., 2017). As microbial energy sources become exhausted and communities begin to turn over, the nitrogen-rich molecules contained in microbial byproducts and necromass have a similar range of fates as plant compounds, depending on their polymeric structure, solubility, and affinity for bonding to mineral surfaces.

The different structures, fates, and processing pathways of organic molecules after entering the soil leads to SOM that is diverse in its composition, functional properties, and accessibility to decomposers. Organic matter consisting of structural plant and microbial residues free from mineral association is defined as particulate organic matter (POM), the low molecular weight compounds in the soil solution are defined as dissolved organic matter (DOM), while the organic matter found in fine mineral associations is defined as mineral-associated organic matter (MAOM). While arguably there are no 'uniform' SOM fractions, it is useful to describe them as 'primary' when they are distinct from one another and 'secondary' when they are composite, i.e., formed from the aggregation of primary fractions (Christensen, 2001; Denef et al., 2010). Therefore, POM, MAOM, and DOM can be considered primary SOM fractions, as they occur as discrete conceptual units in the soil, and represent a fundamental level of structural complexity (Christensen, 2001). The secretion of extracellular enzymes or extracellular polymeric substances by microbes onto these primary fractions can facilitate further accumulation of soil particles and OM around them, leading to the formation of soil aggregate structures. As soil aggregates are composed of primary structures, they are considered secondary SOM fractions (Christensen, 2001; Denef et al., 2010). Aggregate formation typically occurs through persistent bonding facilitated by organic molecules, polyvalent cation complexes, and aluminosilicate minerals, often around an organic nucleus (Oades and Waters, 1991). Aggregated structures can protect POM by spatial isolation, and have also been shown to facilitate the formation of MAOM as intra-aggregate breakdown and microbial turnover occur (Witzgall et al., 2021). While all SOM will eventually be utilized by the soil microbial community, stoichiometric complexity and diversity, nutrient deficiencies, and oxygen or temperature limitations can moderate the rate and efficiency with which microbial degradation occurs. Thus, POM fractions are often separated between free and occluded in aggregates of different size fractions as a way to get more insight into their turnover time (Six and Paustian, 2014).

Just as the form and function of different SOM fractions vary, the physical characteristics associated with these different SOM fractions, including their size and density, and the size and density of the mineral particles or aggregates they may be associated with, varies among the different fractions (Fig. 1). Taking advantage of these differences enables the separation of MAOM, POM, DOM, and additional fractions, free or as aggregates, by physical procedures. Despite physical SOM fractions being inherently operationally defined, the covariation in physical characteristics of the fractions with the formation mechanisms, response to environmental changes, and chemical composition of the SOM fractions makes them a useful approach to study SOM dynamics.

Fig. 1 Conceptual diagram of the fractions that can be isolated by various physical fractionation techniques. Macro- and micro-aggregates can be isolated using aggregate separation techniques, while mineral associated organic matter (MAOM), free and occluded particulate organic matter (fPOM and oPOM, respectively), heavy coarse organic matter (hcOM) and dissolved organic matter (DOM) require size, density, or combined fractionation techniques.

Isolatable SOM fractions

Particulate organic matter (POM)

Particulate organic matter is the term for the fraction of SOM primarily composed of structural materials of both plants and microbes (e.g., cell walls) that have undergone fragmentation and leaching losses but little to no depolymerization. The structural nature of POM makes it relatively light and coarse, leading to an operational definition of organic material with densities <1.6–1.85 g cm⁻³, and or sizes >53 μm. When separated by density fractionation, POM is often referred to as the light fraction, as its lower density allows separation with floatation. Depending on the type of fractionation scheme and the objectives of a given

study, POM can be further fractionated into free and occluded POM. Free POM is uncomplexed POM that is suspended within the soil matrix and is recoverable prior to soil dispersal methods (Fig. 1). In contrast, occluded POM refers to the fraction of POM that is protected within soil aggregates and is only recoverable following the dispersion of soil structures. Despite these differences in protection, both free and occluded POM fractions have similar sizes and densities.

Mineral-associated organic matter (MAOM)

Mineral-associated organic matter refers to the organic molecules that have sorbed to mineral surfaces or are occluded within highly stable fine microaggregate structures. The dominant molecular components of the MAOM fraction are low molecular weight compounds of plant and microbial origin such as amino sugars and microbial polysaccharides, as well as some larger molecules such as extra polymeric substrates, and microbial necromass. The bulk of organo-mineral associations occur with minerals of the silt and clay size, and as such the operational definition of MAOM is the organic material smaller than 60–50 μm and with a density $>1.6\text{--}1.85\text{ g cm}^{-3}$. This fraction is often referred to in the literature as the heavy fraction when separated by density methods, or the silt and clay fraction when separated based on size. The organo-mineral bonds generally protect MAOM from microbial degradation, but recent work has shown that a fraction of MAOM can actively exchange with the soil solution. Previously, chemical methods such as acid hydrolysis have been used to quantify the amount of MAOM that is stable in its bonds and not actively exchanging with the soil solution (Ramnarine et al., 2018), but new methods for separating the exchangeable pool are actively being developed. Recent advances indicate that methods such as the application of oxalic acid or controlled incubations could provide another method of quantifying the ratio of exchangeable vs. stable MAOM (Jilling et al., 2018).

Other primary SOM fractions

Dissolved organic matter

Dissolved organic matter (DOM) accounts for only about 1–2% of the total organic matter within a soil at a given time and is procedurally defined as the organic molecules that are water soluble and smaller than 0.45 μm . Some methodologies enable the direct measurement of DOM by extractions or centrifugation, though dissolved organic carbon (DOC) is often calculated as the difference between bulk soil carbon and the cumulative carbon recovered after fractionation (Zimmermann et al., 2007). It plays an important role as both a microbial energy and nutrient source, and as a precursor to MAOM formation.

Heavy coarse organic matter

A heavy ($>1.6\text{--}1.85\text{ g cm}^{-3}$), coarse ($>60\text{--}50\text{ }\mu\text{m}$) organic matter fraction (hcOM) is isolated as another primary SOM component together with the POM and MAOM fractions when the fractionation scheme used includes both a size and a density separation (Mosier et al., 2021). This fraction has previously been termed both ‘heavy POM’ and ‘coarse MAOM’ and may consist of low molecular weight compounds sorbed to iron (Fe) or manganese (Mn) coatings on the outside of sand grains, microbial biofilms secreted on large primary particles, or POM encrusted with a mineral coating. The composition of this fraction varies depending on site characteristics, dispersion methods, and soil mineralogy. Although this fraction tends to account for a small percentage of the total soil organic carbon, it represents an important consideration when choosing a fractionation method. When size separations are used, it will become part of the POM fraction, but when density separations are used, it becomes part of the MAOM fraction. Ongoing research is attempting to characterize better this fraction and assign its functional role in the greater SOM pool, but currently it requires site-specific understanding to assess (Samson et al., 2020).

Soil aggregates

Cohesion and fragmentation processes in the bulk soil lead to the formation of soil aggregates, groups of primary particles (i.e., POM, hcOM, and MAOM) that are more strongly attached to each other than to other particles in the soil matrix. Aggregates vary in size and are often classified either as microaggregates (53–250 μm) or macroaggregates (250–8000 μm), depending on their diameter, or on the basis of their stability under applied stressors, such as repeated sieving or wetting and redrying. More stable aggregates retain their structure, and less stable ones disintegrate into the constituent primary fractions. Separating soils into different aggregate size and stability fractions helps our understanding of SOM structure and can give important insight into SOM formation and cycling processes. However, because of the composite nature of aggregates, they cannot be quantified together with and compared to the fractions they are composed of. Therefore, aggregates must be dispersed during the fractionation procedure to account for and compare the SOM content of primary fractions. Combined methods have been developed that introduce dispersion at different stages to isolate primary fractions that occur within different aggregate size fractions, which can give insight into primary fraction protection and controls on heterogeneity in primary fraction turnover time.

Other SOM fractions not isolated by physical fractionation methods

In contrast to the physically defined fractions described above, some SOM components have distinct chemical and functional properties, but lack distinct physical characteristics, and can be found distributed across physical fractions. Microbial biomass and pyrogenic organic matter are two such components. A small and ubiquitous SOM component, microbial biomass turns over

quickly, and its methodological quantification is beyond the scope of this chapter (see Horwath and Paul, 1994 for further discussion). Pyrogenic organic matter (PyOM) is present in most soils and results from the transformation of plant material into highly condensed aromatic rings by combustion at high temperatures. These aromatic structures are resistant to decomposition, requiring large amounts of energy to sever the chemical bonds. Even in systems that do not burn regularly, PyOM can be relatively abundant across the primary soil fractions, with potential to influence the calculation of mean residence time. This ubiquity indicates that PyOM should often be considered more fully in SOM studies (Lavallee et al., 2019). Given the strong persistence of PyOM and its distinct properties from POM and MAOM it would be advisable to separate it from these fractions; the combined use of hydrogen pyrolysis or Mid-IR spectroscopy with physical fractionation (Lavallee et al., 2019; Sanderman et al., 2021) hold promise for the feasibility of this approach at scale.

Aggregate fractionation methods

Various methods of aggregate fractionation have been proposed, primarily based on separation by size. Box 1 provides an in-depth overview of the aggregate separation scheme developed by Six et al. (1999), which has been identified as reproducible and consistent during multi-laboratory comparison studies (Poeplau et al., 2018). A key consideration during aggregate fractionation is the method by which aggregates are separated during fractionation. One method of aggregate separation and isolation is 'slaking', the process of rapidly immersing air-dried soil in water before rapidly removing it. Air pressure within the aggregate is increased upon rapid submersion, and low stability aggregates are disrupted. In contrast, rewetting of aggregates prior to fractionation by gradual capillary saturation to a water content of 105% of the bulk soil does not readily disrupt low stability aggregates, as the disruptive force applied to the soil is much less than when slaked. In laboratory comparisons of slaking vs. rewetting methods, more microaggregates were recovered in slaked soils than in rewetted ones, and macroaggregate recovery was increased in the rewetted soils (Six et al., 2000).

The process of separating aggregates is performed by sieving for a set amount of time. Both dry sieving of undispersed soils and wet sieving of air-dried (slaking) or sieving of rewetted soils have been used to separate aggregate size fractions. However, dry sieving has been shown to overestimate enzyme activity, while wet-sieving has been shown to indicate more significant differences between isolated fractions (Nahidan and Nourbakhsh, 2018). Following separation of aggregate size classes, dispersions and further fractionation can be performed to isolate primary fractions and separate the SOM fractions that are occluded within aggregates vs. suspended in the soil matrix (Six et al., 1998).

Primary particle fractionations

Dispersal methods

A key step during all physical primary particle fractionations is aggregate dispersal, for which several methods have been developed. The objective of all soil dispersal techniques is to disrupt the bonds between soil minerals such that the secondary aggregate structures are broken down into the constituent fractions. In practice, full dispersion is rarely if ever achieved; bonds in the microaggregate structures composed of silt and clay particles require tremendous energy to break, and as such some microaggregates will remain following the application of all dispersion methodologies. However, these fine aggregates (<53 µm) function similarly to organic matter bonded to silt and clay-size particles, and the application of enough energy to disrupt these fine aggregates would probably damage the primary minerals, leading to transfer of carbon between fractions. Thus, after conventional aggregate dispersion they are considered part of the MAOM fraction. A common side-effect of dispersal and liquid-mediated fractionation methods is the possibility of carbon transfer between fractions, which should be minimized at all steps of dispersal. Here we review the methodology for and the benefits and disadvantages of two of the most common types of soil dispersal methods: mechanical shaking and ultrasonic dispersion.

Mechanical shaking

Mechanical shaking methods of soil dispersal apply kinetic energy generated by sustained agitation to soils suspended in a liquid to fragment and disperse aggregates into smaller, primary particle fractions. Mechanical shaking can be performed in either a horizontal reciprocal shaker, which transfers energy to the soil solution by consistent movement back and forth along a single axis, or in an end-over-end shaker, which uses the falling of the soil solution to produce the energy necessary for dispersion. For reproducibility, shaking should be reported in terms of oscillations or rotations per minute, however, the shaking intensity is often reported qualitatively in the literature. Though to the authors' knowledge no studies have looked explicitly at shaking intensity, the consensus across studies indicates that shaking should be performed at a low-to-moderate speed (e.g., 110 oscillations per minute). The addition of glass beads increases the energy transfer from the shaker to the soil suspension and better disperses soils. There is a risk of fragmenting POM when using glass beads, however, and of puncturing vacuoles in vegetative tissue causing it to become smaller and denser, possibly leading to a small transfer of POM to the MAOM during fractionation (Diochon et al., 2016).

Several liquids have been used as a medium for mechanical dispersal, including water (H₂O), sodium hexametaphosphate ((NaPO₃)₆; SHMP), and sodium polytungstate (Na₆[H₂W₁₂O₄₀]; SPT). Sodium hexametaphosphate is the most commonly used soil dispersant. Its molecular structure allows for the formation of unassociated complexes with cations and reduces the flocculation

Box 1 Methods for physical fractionation of aggregates based on aggregate size.Methodology

- 1) Weigh out approximately 50 g of air dried, bulk soil that has been sieved to pass through a 2-mm sieve and record weight to the 0.01 g.
- 2) Place weighed soil on top of a 250- μ m sieve, and place the sieve into a large, clean container.
- 3) Fill the container with DI water until there is ~2 cm of liquid covering the sieve.
- 4) Allow sample to sit for 5 min in the water.
- 5) After 5 min, gently move the sieve up and down 50 times over the course of 2 min. Aggregates should just come out of the water on the upward stroke, and the sieve should not hit the bottom on the downward stroke.
- 6) Remove sieve from water and backwash aggregates that remain on top of the 250- μ m mesh into a pre-weighed container.
- 7) Place a 53- μ m sieve in a second, large, clean container, and then gently pour the effluent from the first container over the sieve.
- 8) Repeat step 5, and then backwash the aggregates that remain on the 53- μ m sieve into a pre-weighed container.
- 9) Transfer effluent to 1-L centrifuge bottles, and centrifuge for 15 min at 3220 RCF.
- 10) Carefully pour off supernatant, and transfer silt and clay in bottles to pre-weighed container.
- 11) Place tins in oven to dry at 50 °C until all water has evaporated, and then weigh. The first sample collected is the macroaggregate fraction, the second the microaggregate fraction, and the third the silt and clay fraction.

Materials Required

- 40–50 g soil sieved < 2 mm
- 1 250- μ m sieve
- 1 53- μ m sieve
- DI water
- 2 clean large pans (e.g., plastic oil pans)
- 1-L centrifuge bottles
- 3 large, pre-weighed sample tins

of clay minerals. However, the use of SHMP as a dispersant for SOM fractionation techniques can add a level of complexity and error to the results. Therefore, additions of SHMP to the soil must be either rinsed out of the soil by repeated washing with DI water or maintained in the sample throughout the analysis. Rinsing of the soils can lead to SOC leaching from fractions, compromising both total carbon recovery and the accuracy of results. Maintaining SHMP in the organic matter fractions can also lead to artificially inflated recoveries when examined on a mass basis, possibly obscuring loss during the fractionation process that could indicate poor recovery.

Shaking in water avoids the potential to change the chemical character of SOM fractions or add mass that may skew recoveries. A recent study indicated poor reproducibility with water extractions alone, however, as without a complementary dispersal additive water may not have the power to disrupt aggregates fully (Just et al., 2021). Mechanical shaking can also be performed in SPT, which can be convenient when SPT is used in further fractionation steps. However, similar to SHMP, SPT must be rinsed from samples

prior to further analysis. Reviews of rinsing procedures have demonstrated leaching of carbon from all fractions may occur, leading to underestimation of organic carbon across fractions (Plaza et al., 2019). In addition, a review of SPT has shown that it can contaminate samples with non-native nitrogen (N) and tungsten (W), especially in the mineral-associated fraction (Kramer et al., 2009). Mechanical shaking is a good method to use across a variety of soils since its dispersal power is less dependent on soil type than the alternative ultrasonic vibration presented below. For any method, the operator should use it with care and adjust shaking time and intensity, number of beads and rinsing of dispersal agent to minimize drawbacks.

Ultrasonic vibration

The second common method of soil dispersion is sonication, in which ultrasonic vibrations are applied to soil suspensions, disrupting bonds, and separating soil components. The general application of this method introduces ultrasonic waves into a solution containing non-dispersed soils. As the waves travel through the solution, alternating pressure conditions are created. Small bubbles are formed in low pressure areas, which then implode as the bubbles encounter high pressure areas. This implosion, and the force associated with it, disperses the secondary structures as the water jet that is created can have velocities that exceed 100 m sec^{-1} . One of the central benefits of this method is that it provides quantitative values of the amount of force used and is therefore theoretically reproducible. Soils with a high clay content create tightly bound microaggregates, which require a higher dispersion energy than more coarse soils. Therefore, the amount of force needed for proper dispersal varies between soil textures, mineralogies, and structures, and must be calibrated prior to experimentation. The amount of sonication energy used to break aggregates from secondary into primary structures spans a broad range. In a review, Kaiser et al. (2010) report sonication energies used for dispersal ranging from 60 to $10,000 \text{ J cm}^{-3}$. Researchers who work consistently with the same soils may benefit from using the calibrated values provided by sonication methods, large scale projects that encompass a variety of global soils with variable physiochemical characteristics will require approaches that are more consistent across samples.

Carbon transfer between fractions can occur when using sonication dispersal techniques as well. At the POM level, sonication can significantly fragment structural litter particles, leading to redistribution among all size fractions. Using energy levels between 280 and 420 J cm^{-3} , Oorts et al. (2005) found that there was a transfer of 35–37% of the nitrogen and of 20–31% of the carbon from coarse POM into smaller size fractions following dispersal. However, this damage and subsequent carbon transfer has been found at energy levels as low as 90 J cm^{-3} (Amelung and Zech, 1999). This transfer can have important implications depending on ecosystem type and experimental goals. Even in systems where the coarse POM fraction is relatively small, the fragmentation and redistribution of this fraction has large implications for isotopic studies. Primary SOM fractions, because of differences in their formation, degree of microbial processing, and persistence, often have distinct isotopic values. As such, isotopic techniques such as ^{14}C that quantify age and turnover time, or ^{13}C and ^{15}N that quantify origin and degree of transformation can be considerably compromised by the transfer of even small amounts of organic matter among fractions.

For soil particles, excessive sonication energy can potentially damage the crystalline structure of minerals, resulting in bias in the recovery of different SOM fractions based on size. Several studies have documented fragmentation of sand separates into smaller fractions, especially as sonication energy exceeds 700 kJ cm^{-3} . Additional evidence of damage to silt particles has also been observed with scanning electron microscope (SEM) techniques (Kaiser et al., 2012). Currently, there is no evidence that sonication can fragment particles smaller than $20 \mu\text{m}$ (i.e., the clay fraction). However, the energy required to disperse small clay aggregates may exceed the energy that could fragment larger particles, such that these two extremes must be balanced. Calibration of the sonication energy is an important step in the dispersal process for optimizing aggregate dispersal while minimizing the amount of carbon transfer between particle-size classes and SOM fractions.

Size fractionations

Several fractionation methods that use particle size as a differentiating factor between primary fractions have been established. These methods aim to separate primary SOM fractions after dispersal by sieving with different mesh sizes (Fig. 2). Typically, sizes ranging between 53 and $60 \mu\text{m}$ are used to separate POM ($>53 \mu\text{m}$) from MAOM, but a cutoff at $20 \mu\text{m}$ to separate the fine MAOM is also used. In the review of fractionation methods by Poeplau et al. (2018), particle-size fractionation was found to be an effective way of isolating fractions that differed in their turnover times. The methodology of the size fractionation technique deployed by Cotrufo et al. (2019) is shown in Box 2.

Size fractionations are relatively simple and tend to have limited mass loss during the procedure. Furthermore, they require a low level of skill and laboratory infrastructure, are cost effective, and throughput can be relatively high ($25\text{--}30$ samples day^{-1}). Size fractionations have been used in several studies as an effective method of separating two functionally distinct SOM pools, i.e., POM and MAOM. They provide important insight about the formation and persistence of SOM in response to treatment. Those studies that have a large number of samples, or that expect a moderate to large size effect in response to treatment in either the MAOM or POM fraction are well suited for size fractionation methods. However, size fractionations can be limited in scope depending on the research objectives of a given study. Size fractionation methodologies are unable to separate occluded POM from free POM and cannot be used to isolate the hcOM fraction. Further, the DOM fraction will be grouped with the MAOM fraction if not isolated prior to the size fractionation.

Fig. 2 Demonstrations of fractionation techniques and examples of equipment used. (A) Aspiration of the light fraction floated in SPT using vacuum filtration. (B) Transfer of light fraction from nylon filter to pre-weighed pan. (C) Wet sieving to separate MAOM from hcOM (combined fractionation) or POM (size fractionation). (D) Back washing of hcOM (combined fractionation) or POM (size fractionation) fraction into pre-weighed pans from after completion of sieving.

Density separations

An alternative method to size fractionations is to take advantage of the differences in density of mineral particles and partially decomposed litter fragments. Organic matter has a lower density than minerals, and when submerged and centrifuged in a liquid of a known density, it floats while the mineral-associated portion of the sample sinks. The lighter fraction can then be aspirated and analyzed separately from the heavier fraction (Fig. 2). Sequential density fractionations combined with dispersion can also be used to separate the free POM from the aggregate-protected POM. In this case, the soil sample is initially subjected to little to no

Box 2 Methods for physical fractionation of POM and MAOM based on primary particle size.Methodology

- 1) Weigh out 5.25–5.75 g of air dried, bulk soil that has been sieved to pass through a 2-mm sieve into a pre-weighed centrifuge tube, and place in 60 °C oven overnight.
- 2) Take samples out of oven, cool in desiccator, and weigh samples + tubes to 0.01 g.
- 3) Add 12 small glass beads to the tube, then add 0.5% sodium hexametaphosphate to the 30 mL line and cap samples.
- 4) Shake the samples for 18 hours $\pm$ 15 min at $\sim$ 112 oscillations per minute.
- 5) Place the 2000- μ m sieve on top of the 53- μ m sieve in a clean, large shallow pan. Shake sample to ensure all soil is in solution, then pour sample over the nested sieve.
- 6) Retrieve glass beads from 2000- μ m sieve and wash any soil material onto the 53- μ m sieve.
- 7) Rinse the 53- μ m sieve with DI water until rinsing water runs clear, making sure also to rinse the sides of the sieve.
- 8) Back rinse the material remaining on top of the 53- μ m sieve into a pre-weighed weighing pan and place in the oven at 60 °C.
- 9) Transfer the effluent from the large shallow pan into a pre-weighed weighing pan and place in oven at °C.
- 10) Once samples are completely dry, weigh and ensure that recoveries fall between 95% and 105% of sample mass. If recoveries are large, re-dry and reweigh samples.
- 11) If recoveries are acceptable, samples can be ground using a mortar and pestle and prepared for further analysis.

Materials Required

- 50 mL conical centrifuge tubes
- 0.5% sodium hexametaphosphate
- Pre-weighed weighing pans
- 2000 and 53- μ m sieves.
- DI water
- Large, shallow pan

dispersion prior to density flotation and collection of the free POM. The sample is then more thoroughly dispersed, releasing low-density material that was occluded in aggregate structures, and the occluded POM can be separated by a second density flotation.

The most common solution used in density fractionations is SPT and, as mentioned above, some procedures also call for its use as a dispersing agent. Previous studies have also employed sodium iodide (NaI) as the heavy liquid for density fractionations, but found that the use of NaI may increase the pH of the soil solution, which has the potential to disrupt organo-mineral bonds and facilitate intra-fraction C transfer (Plaza *et al.*, 2019). By changing the amount of water added to heavy liquid, the density can be manipulated to achieve different fractionation outcomes. Previous research by Cerli *et al.* (2012) highlighted the differences in recovery of the light fraction across different densities. Their results suggest that a density of 1.6 g cm⁻³ is the optimal density for achieving maximum floatation of organic material and to minimize the presence of minerals in the light fraction. Most studies use densities of 1.8–1.85 g cm⁻³ to maximize recovery of organic material not associated with minerals and to improve floatation. Even

higher densities have been suggested but the risk of contamination by mineral particles increases as density increases. The ultimate density chosen for a given study should be as close to the maximum density of the organic materials present as possible, while minimizing potential mineral contamination of the light fraction. Calibration for individual sites may be necessary.

Sequential density fractionations, with progressively increasing densities, on dispersed soils have also been used to separate mineral-associated fractions with distinct mineralogical components after the removal of the light fraction, as demonstrated by Sollins et al. (2009). By increasing the density of the suspension liquid with each successive fractionation, it is possible to isolate a range of different MAOM fractions, including short-range order minerals such as allophanes (density: $>2.0 \text{ g cm}^{-3}$), high activity phyllosilicates such as smectite (density: $>2.3 \text{ g cm}^{-3}$), framework silicates such as quartz and feldspars (density: $>2.7 \text{ g cm}^{-3}$), and oxides such as hematite and goethite (density: $<3.0 \text{ g cm}^{-3}$). This increased separation of the MAOM fraction can give further insight into the controlling factors on SOM persistence and formation across different soil environments. However, with each additional density flotation, the risk of decreasing recovery or carbon transfer between fractions becomes greater. Further, density fractionations are time intensive, as SPT must be rinsed from the samples several times during each step, expensive, and require greater laboratory skill to execute compared to size fractionations.

Overall, density fractionations are a useful tool for separating organic and mineral particles that may not differ in size but have other contrasting properties. Studies that are focused on the differences between formation pathways and cycling of POM will benefit from density separations, as it enables explicit isolation of the most plant derived fraction, in contrast with size separations. Studies that concern changes in management or land use in particular may also benefit from density fractionations because the light fraction is the most rapidly altered by shifts in inputs and disturbance.

Combined separations

Aggregate, size, and density fractionations may be combined to separate the key functional organic matter pools and elucidate mechanisms of SOM formation and stabilization. These fractionation procedures allow for increased isolation of pools that may be grouped together in size or density fractions, such as hcOM. In addition, when size and density are combined with aggregate fractionation, they enable a greater degree of differentiation of the organic carbon that is either occluded within aggregates in mineral and particulate forms, or free in the soil matrix (Six et al., 1999). These characteristics of the combined size-density fractionations provide a scheme that can approach the fractions identified more closely in the conceptual framework than size or density fractionations alone. In the comparison study by Poeplau et al. (2018), fractionation methods that combine a size with a density separation following complete dispersion were very effective in differentiating fractions with different turnover times, had average mass recoveries greater than 95%, and were reproducible across multiple fractionations. A typical scheme combining size and density fractionation schemes isolated four fractions: DOM, IPOM, hcOM, and MAOM (Mosier et al., 2021; Box 3). As with the density fractionation methods, further sequential density separations could be done to isolate particular mineralogical constituents. Similarly, further size fractionations could also be performed to isolate particular subclasses of particles (e.g., fine clay vs. silt, etc.). However, adding successive density or size cutoffs can decrease the overall efficacy of the fractionations; the risk of leaching carbon from the samples or transferring between fractions increases with the addition of further washing, shaking, or centrifugation steps (Poeplau et al., 2018).

Chemical-free physical fractionations

There has been some recent research towards the development of chemical free physical fractionation methods because of the complications that can arise with chemical dispersants and density floatation media (Kaiser et al., 2010). Fractionation methods that immerse soils in any liquid can lead to redistribution of carbon between fractions, therefore, these methods present an alternative to the use of SHMP or SPT, possibly reducing the risk of carbon redistribution. This method uses a series of nested sieves, separating particles into six particle classes, ranging from 2 to $<0.315 \text{ mm}$. Soils are sieved prior to analysis, but not otherwise dispersed. A glass petri dish is then charged by rubbing it with cotton, and each particle class is placed separately on a clean stone plate. The charged petri dish is then placed 2–5 cm above the stone plate and moved slowly over the sample. The distance between the charged surface and the size fractions must be calibrated manually for each sample to avoid the attraction of mineral particles. Following the attraction step, organic fractions must be examined visually for mineral contamination, and mineral particles removed. This procedure is then repeated five times for each fraction.

When tested across several arable and forest soils, this method resulted in considerable variation in the amount of organic matter separated from each of the sieved mineral fractions (CV: 0.3–174%; Kaiser et al., 2009). However, when examined across mineral fractions, the variability accorded with the reproducibility reported for size and density fractions. Taken in tandem, these measures indicate a useful methodology for the separation of POM and MAOM, but may be limited in their ability to separate different POM fractions (i.e., occluded vs. free POM). These methods are not as widely tested as those presented in previous sections but represent an interesting and important line of inquiry that should be further explored by research groups. Given the potential drawbacks associated with sonication, shaking, and the use of SPT, non-aqueous non-dispersive methods may provide increased insight into SOM pools moving forward, as well as the role of SOM in facilitating N exchange. However, the time needed per sample, together with the requirement of manual calibration during each successive pass with the charged petri dish makes these methods cumbersome when dealing with large sample sizes.

Box 3 Methods for combined density and size fractionation of primary SOM fractions.Methodology

- 1) Weight out 5.5–6 g air dried, 2-mm sieved soils into a pre-weighed, acid washed centrifuge tube, and place tubes in 60 °C oven overnight.
- 2) The following day, weigh samples on a 4-place scale, and then add DI water to the 35 mL line and shake for 15 min on low (~112 oscillations per min).
- 3) Rinse tubes and caps with DI water, and then balance tubes and centrifuge at 2325 RCF for 15 min.
- 4) Pour supernatant over a 20- μ m nylon filter on a filtration unit, and transfer filtered liquid to a clean, new centrifuge tube.
- 5) With a squirt bottle, rinse any light fraction that accumulated on the filter into a small, pre-weighed pan.
- 6) Fill centrifuge tubes to 25 mL with 1.85 SPT and add 12 glass beads. Resuspend soil pellet and shake on low for 18 h.
- 7) After shaking, rinse tube cap and side with SPT, and then balance tubes and centrifuge at 2325 RCF for 30 min.
- 8) Using a vacuum filter, aspirate the light fraction and SP T over a 20- μ m nylon filter.
- 9) Transfer light fraction from filter to pre-weighed pans using a squirt bottle, and place pans in the 60 °C oven to dry.
- 10) Add DI water to the centrifuge tube up to the 30-mL line and resuspend the pellet. Rinse cap and sides, then balance and centrifuge for 20 min at 2325 RCF.
- 11) Pour supernatant off, and repeat the processes, adding water, suspending the pellet, and then centrifuging for 20 min at 2325 RCF. Repeat rinsing process one more time.
- 12) After rinsing, add water to 20 mL line, suspend pellet, and separate fractions by size, as described in steps 5–11 in **Box 2**.

Materials Required

- Pre-weighed 50-mL conical centrifuge tubes
- 0.5% sodium hexametaphosphate
- Pre-weighed weighing pans
- 2000-and 53- μ m sieves
- DI water
- Large, shallow pan
- Centrifuge
- Oscillating shaker
- 4-mm beads
- Sodium polytungstate
- Filtration unit
- 20- μ m nylon filter

Conclusions

Physical fractionation methods provide a means for researchers to isolate functionally distinct fractions of SOM. Unlike chemical and biological fractionation methods, physical fractionation methods take advantage of the inherent properties of both soil particles and organic material to separate SOM with different formation pathways, mechanisms of stabilization, and thus responsiveness to changes and overall persistence. Here we have reviewed several different possible methods for physical fractionations, including those based on particle size, particle density, and aggregate size. All have their pros and cons, and recovery of fraction mass and carbon (or nitrogen) need to be quantified at the end and reported. The methods examined provide a good foundation for functionally meaningful SOM fractionation, and we hope will continue to be improved and expanded upon by researchers moving forward. There are still important research questions that remain unanswered, such as the relationship between efficacy of the fractionation method and soil physiochemical properties, and if what we separate today as ‘primary’ fractions are indeed unique functional units (e.g., POM and MAOM), or are made of contrasting functional structures requiring further separation (e.g., exchangeable and stable MAOM). Continuation of this research will improve the tools at our collective disposal and advance this field further.

Abstract

In this chapter, we focus on low atomic mass stable isotopes that are widely used in soil and environmental studies. These include carbon (C), nitrogen (N), oxygen (O), and sulfur (S). We elucidate how such stable isotopes are used to infer processes, estimate mean residence time of an element in an environmental compartment, and identify sources or relative contribution to a pool. In addition, we describe the basis of the most widespread analytical methods for isotope analyses and report relevant technical advances, which are expected to provide unique insight into biogeochemistry of key elements of life in the near future.

Glossary

Compartment An assemblage of atoms that is not necessarily chemically homogeneous, for example, nitrogen in soil organic matter or in the plant.

Labelling Artificial enrichment or depletion of an isotope in a specific compound or compartment (e.g. the plant).

Moiety In organic chemistry, a part of a molecule.

Pool A compartment containing material that is chemically indistinguishable and equally accessible to plants or to the soil organisms; e.g. soil ammonium pool.

Tracer Substance with atomic or nuclear, physical, chemical or biological properties that enables us to identify, observe or follow various physical, chemical or biological processes.

Key points

- Relevance of stable isotopes of light elements in soil science studies
- Main terminology, notations, and approaches in isotope studies
- The main measurement techniques for isotope ratios
- Relevant examples of application of low atomic mass isotopes (C, N, O, S) in soil science
- Current trends and future development in the application of C, N, O, S isotopes

Introduction

Overview and terminology

Isotopes are atoms of the same element with the same number of protons in the nucleus but different number of neutrons. Therefore, the atomic mass of isotopes of a same element differs by one or more units. The most common isotopes are generally the lightest and are much more abundant (>95 atom percent) than the heavier ones (Table 1).

Isotopes of the same element have qualitatively the same chemical properties, because they have the same number and arrangement of electrons. However, the replacement of an element with one of its isotopes determines slightly different physico-chemical behavior, expressed in changes of chemical reaction rates or equilibrium constants. These differences are called ‘isotope effects’, and are proportional to the relative mass difference between isotopes for most processes. Mass-independent isotope effects of O and S can take place e.g. in the stratosphere, and have proven to be very useful to trace atmospheric inputs to terrestrial ecosystems (see Section “Oxygen in nitrate and sulfate”). For light elements (Table 1), the isotope effects are greater because their difference in mass is proportionally bigger. Such partitioning of isotopes translates into detectable variation in isotopic composition of molecules, chemical species, and phases (e.g. soil water vs water vapor). Naturally occurring or artificially induced variations in isotopic composition of molecules can provide insight into processes affecting environmental compartments or pools.

Molecules that differ only in their isotopic composition or the intramolecular position of the isotopes but having the same chemical formula are generally called isotopocules (isotopically substituted molecules). Molecules that differ only in isotopic composition are called isotopologs (isotopic analogs), and often present distinct masses. Some molecules, such as nitrous oxide (N₂O), include isobaric isotopologs either having the same nominal mass, e.g. ¹⁴N¹⁵N¹⁶O and ¹⁴N¹⁴N¹⁷O, or the same exact mass, e.g. ¹⁴N¹⁵N¹⁶O and ¹⁵N¹⁴N¹⁶O. When isotopocules differ only in the position of the isotope but the masses are the same, they are called isotopomers (isotopic isomers; IUPAC, 1997). An excellent reference for the correct use of terminology is given in Sharp (2017, Table 2.1).

Why are stable isotopes useful in soil science studies?

Low atomic mass stable isotopes of carbon (C), nitrogen (N), oxygen (O), and sulfur (S) are used to assess biotic and abiotic processes that characterize the biogeochemical cycles of such elements. Less commonly used light elements are hydrogen, lithium, boron, silicon, magnesium, and chlorine.

Low atomic mass stable isotopes are used to (i) infer processes or process rates, e.g. heterotrophic nitrification (see Section “Nitrogen”), (ii) estimate mean residence time of an element in an environmental compartment or pool, such as carbon in soil organic matter (see Section “Carbon”), or (iii) identify sources or relative contribution to a pool, as in studies of soil erosion or atmospheric deposition (see Sections “Nitrogen” and “Sulfur”). Isotopes are particularly useful to trace fluxes of an element in the environment when these fluxes are much smaller than the stocks. In some cases, isotopes are an irreplaceable research tool, for example, to estimate gross nutrient fluxes, such as gross mineralization rate. Finally, isotope data are used to constrain biogeochemical models.

We report here relevant although not exhaustive applications of C, N, O, and S stable isotopes in soil science studies.

Table 1 Isotopes widely used in soil science and relative international standards.

Element	Isotope symbol	Atomic mass <i>u</i> , mol g ⁻¹	Nominal abundance atom percent (%) ^a	Relative mass difference %	Standard value <i>R</i> × 10 ⁶ ^b	Standard acronym and identification
Hydrogen	¹ H	1.007825032	99.984426	100	155.76 ± 0.10	V-SMOW, Vienna-Standard Mean Ocean Water

^b± 95% confidence interval.

How to express abundances of isotopes at natural abundance and in enriched samples, and how to express the isotopic fractionation

Stable isotope studies are based on measurements of changes in abundance of different isotopes in a compound, phase, or material. The abundance can be expressed in different ways as summarized in Table 2 (reviewed also in Werner and Cormier, 2022).

In recent years, the use of isotope delta with the per mill notation has been debated (Table 2). This notation is the preferred one in most studies using stable isotopes at natural abundance, even though the ‰ does not represent a unit in the International System of Units (SI; Brand and Coplen, 2012). Coplen (2011) recommended that the multiplicative factor 1000 should be avoided. An alternative option would be to use a new unit milli-Urey, mUr, to replace the ‰ sign (Brand and Coplen, 2012). In this chapter, after considering its still widespread use, we will refer to isotope delta in the per mill notation.

All the notations reported in Table 2 have their distinct application, depending on the study. When working with samples enriched in heavy isotopes (tracing experiments, see Section “Natural abundance and labelling approaches”), use of the delta notation is not advisable, and the atom fraction or atom percent should be chosen.

Isotope delta values behave ‘linearly’ in equations for mass balances, but only when all compounds are at natural abundance. When used for samples or standards enriched in heavy isotopes, delta values will generate errors (Corso and Brenna, 1997). In these instances, the *isotope phi* value can overcome this limitation and is recommended. For an example of calculation, see Box 1. Further details on the use and significance of *phi* are given in Werner and Cormier (2022).

Isotope effect and isotopic fractionation

Fractionation of isotopes is defined by Hoefs (2021) as “the partitioning of isotopes between two substances or two phases of the same substance with different isotope ratios”.

Isotopic fractionation is caused by both physical reactions, including evaporation or diffusion, and chemical reactions. Isotopic fractionation processes can be further divided into: (i) equilibrium or thermodynamic isotopic fractionation, also known as equilibrium exchange reactions, and (ii) kinetic isotopic fractionation.

Table 2 Most common notations for isotopes and measures to express isotopic composition and isotopic fractionation in numbers. In this case, we take the example of carbon stable isotopes, ^{12}C and ^{13}C .

Name	Formula	Notes; References
<i>Isotope notation</i>		
Atom fraction x	$x(^{13}\text{C})_A = \frac{n(^{13}\text{C})_A}{n(^{12}\text{C})_A + n(^{13}\text{C})_A}$	Dimensionless; Coplen (2011)
Atom percent ‰	$\text{‰}(^{13}\text{C})_A = \frac{n(^{13}\text{C})_A}{n(^{12}\text{C})_A + n(^{13}\text{C})_A} \cdot 100$	Old term, according to Coplen (2011) it should be replaced by the atom fraction x ; however, it is still widely used and accepted by authors and reviewers; Coplen (2011)
Atom percent excess	$\text{APE} = \text{‰}(^{13}\text{C})_A - \text{‰}(^{13}\text{C})_{\text{control}}$	Coplen (2011) and references therein
Isotope ratio	$^{13}R_A = \frac{^{13}\text{C}}{^{12}\text{C}}$	Coplen (2011) and references therein
Delta notation	$\delta^{13}\text{C}_A = \frac{^{13}R_A - ^{13}R_{\text{Std}}}{^{13}R_{\text{Std}}}$ $\delta^{13}\text{C}_A = \left(\frac{^{13}R_A}{^{13}R_{\text{Std}}} - 1 \right)$	Until recently, a multiplicative factor 1000 was included in these equations: see discussion in section “How to express abundances of isotopes at natural abundance and in enriched samples, and how to express the isotopic fractionation”; McKinney et al. (1950) and Coplen (2011)
Isotope ratio from delta	$^{13}R_A = (\delta^{13}\text{C}_A + 1) \cdot ^{13}R_{\text{Std}}$	–
Isotope phi	$\varphi^{13}\text{C}_A = \frac{\delta^{13}\text{C}_A}{^{13}R_A + 1}$ $\varphi^{13}\text{C}_A = \frac{x(^{13}\text{C})_A}{^{13}R_{\text{Std}}} - 1$	Corso and Brenna (1997) and Brand and Coplen (2012)
<i>Isotopic fractionation notation</i>		
Alpha ^a	$\alpha^{13}\text{C}_{\frac{B}{A}} = \frac{^{13}R_B}{^{13}R_A} = \frac{\delta^{13}\text{C}_B + 1}{\delta^{13}\text{C}_A + 1}$	Friedman and O’Neil (1977)
Epsilon ^a	$\varepsilon^{13}\text{C}_{\frac{B}{A}} = \alpha^{13}\text{C}_{\frac{B}{A}} - 1$	Can be expressed in 10 ³ or milli-Urey
Per mill isotope fractionation	$10^3 \ln \alpha = 1000 \ln \left(\alpha^{13}\text{C}_{\frac{B}{A}} \right)$	Commonly used in geochemical studies; Friedman and O’Neil (1977)
Relation among isotopic fractionation notations	$\Delta^{13}\text{C}_{\frac{B}{A}} = \delta^{13}\text{C}_B - \delta^{13}\text{C}_A \approx \varepsilon^{13}\text{C}_{\frac{B}{A}} = \alpha^{13}\text{C}_{\frac{B}{A}} - 1 \approx \ln \left(\alpha^{13}\text{C}_{\frac{B}{A}} \right)$	Friedman and O’Neil (1977)

n = number of atoms; A and B = compounds A and B ; Std = standard (see Table 1 for list of standards); control = control compound (see examples about ^{15}N in Section “Nitrogen”); $\ln$ = natural logarithm.

^aIn the following equilibrium oxygen isotope exchange reaction between calcite and water: $1/3 \text{CaC}^{16}\text{O}_3 + \text{H}_2^{18}\text{O} \rightleftharpoons 1/3 \text{CaC}^{18}\text{O}_3 + \text{H}_2^{16}\text{O}$ the $\alpha^{18}\text{O}_{\text{calcite/water}}$ at 33.7 °C is 1.02849 ± 0.00013 and ε is equal to: $\alpha^{18}\text{O}_{\text{calcite/water}} - 1 = 0.02849$ and can be expressed as 28.49‰ (data taken from Coplen, 2011).

Box 1 The use of *isotope phi*.

Let us hypothesize that we need to obtain 100 mL of ^{18}O -labelled water (W_i) with a delta value $\delta^{18}\text{O}$ of +120‰ ($R_i = 0.002245835$) by diluting labelled water (W_{labelled}) with an ^{18}O atom percent of 98% with unlabelled water (W_{unlab}), having a $\delta^{18}\text{O}$ of -11‰ and $R_{\text{unlab}} = 0.001985158$. The $\delta^{18}\text{O}$ values are expressed against the VSMOW standard, which has an $R_{\text{std}} = 0.00200521$. Note that to calculate ϕ , the $\delta^{18}\text{O}$ in per mill, should be divided by 1000.

$$\phi(W_{\text{labelled}}) = (0.98/0.00200521) - 1 = 487.73$$

$$\phi(W_{\text{unlab}}) = (-0.011)/(0.001985158 + 1) = -0.01$$

$$\phi(W_i) = (0.120)/(0.002245835 + 1) = 0.12$$

$$100 \text{ mL } W_i (\phi=0.12) = x \text{ mL } W_{\text{lab}} (\phi=487.73) + (100 \text{ mL} - x) W_{\text{unlabelled}} (\phi = -0.01)$$

Solving the mass balance equation for x , we find that we need 0.03 mL of ^{18}O labelled in 99.97 mL of unlabelled water.

Equilibrium isotopic fractionation involves reactions at chemical equilibrium, i.e. reactions in which forward and backward rates are equal. Note that isotopic equilibrium usually takes longer to be established than chemical equilibrium (Rishavy and Cleland, 1999). During equilibrium reactions, the heavier isotope tends to concentrate in the phase or molecule with stronger covalent bonds (i.e. more energetic). In equilibrium exchange reactions, the compound with the higher oxidation state or more condensed state will also be enriched in the heavier isotope (Coplen, 2011). For example, carbon dioxide is enriched in ^{13}C compared to methane, and liquid water is enriched in ^{18}O and ^2H relative to water vapor. Equilibrium exchange reactions typically occur in closed and well-mixed systems. A typical example is the oxygen isotope exchange between liquid water and CO_2 in a closed container. Once the reaction reaches thermodynamic equilibrium, the reactants and products end up with different isotopic composition, because ^{18}O forms a stronger covalent bond with C than with H (Sharp, 2017 and references therein). This has been suggested as the principal effect controlling the composition of oxygen isotopes in atmospheric CO_2 at the global scale (Francey and Tans, 1987). In equilibrium exchange reactions, the shift in isotopic composition of products is constant and inverse with temperature, i.e. greater isotopic fractionation occurs at lower temperatures.

Kinetic isotopic fractionation processes occur in unidirectional and/or irreversible processes or reactions, that is when a reaction proceeds only in the forward direction, the backward reaction being hindered. These include many biological reactions catalyzed by enzymes. Dissimilatory sulfate reduction by sulfate-reducing bacteria or mineralization of phosphoesters by phosphatase enzymes are examples of kinetic isotopic fractionations mediated by enzymes.

Reversible reactions not reaching chemical equilibrium will display net isotopic fractionations in between the kinetic and equilibrium ones. A classical example is represented by reactions where the products are constantly removed from the system, such as water evaporation from surface waters to the atmosphere (described by the well-known Craig-Gordon model, Horita et al., 2008).

In kinetic isotopic fractionation processes, the lighter isotope usually accumulates in reaction products, as the lighter isotopes usually react faster and statistically form weaker chemical bonds (Coplen, 2011). In the previous example of water evaporation in an open system, the water vapor is progressively depleted in ^{18}O and ^2H relative to the liquid water. Kinetic isotopic fractionation might evince magnitudes similar and often greater than those produced from equilibrium exchange reactions. However, when a kinetically controlled reaction goes to completion, the cumulative product ends up with the same isotopic composition as the initial reactant, in other words quantitative reactions do not show any isotopic fractionation.

The isotopic fractionation between two substances or phases, A and B, is quantified by the isotopic fractionation factor alpha (α , Table 2). The commonly used isotopic fractionation, ϵ , similar to the delta value, represents the deviation of α from 1 (Table 2).

Both α and ϵ can refer to equilibrium exchange and kinetic processes. In complex biogeochemical systems, several often unknown reactions or reaction network might result in a 'net' or 'apparent' isotopic fractionation, which is also expressed as α or ϵ (Coplen, 2011).

Note that some authors define α for a kinetic reaction giving the product B from the reactant A as in Table 2, while others use the reciprocal form ($\alpha = {}^{13}R_A/{}^{13}R_B$, here exemplified for carbon isotopes, see Werner and Cormier, 2022). In soil science, both definitions are used. To avoid confusion, it is recommended that the source reference for the definition of α and ϵ are checked and that the equations authors use to express isotopic fractionation are clearly specified.

If the isotopic fractionation is defined as in Table 2, ϵ is positive when the product is enriched in the heavier isotope with respect to the reactant, whereas ϵ is negative when the reactant is enriched in the heavier isotope.

Analytical methods

For studies in soil sciences, solid, liquid, and also gaseous samples are measured for the isotopic composition of the element of interest.

Isotope-ratio mass spectrometry (IRMS) is the most common method of analysis, although other techniques are now being employed for specific samples. A mass spectrometer can determine the isotope ratio of an element by separating moving ionized atoms and molecules in an electromagnetic field on the basis of their mass and charge. The isotope ratio obtained is then compared to that of a reference gas to determine the delta value.

In general, before entering the mass spectrometer in the form of specific inorganic gases, solid and liquid samples have to be processed by methods of elemental analysis (Fig. 1). An elemental analyzer (EA) quantitatively converts the samples into specific gases. Combustion at temperatures between 950 °C and 1050 °C (used to measure C, N, and S isotopes), in the presence of O₂, produces CO₂, N₂/NO_x, SO₂ and H₂O. To yield N₂ quantitatively, nitrogen oxides NO_x need to be reduced on elemental copper (Cu) at T between 600 °C and 650 °C. In addition, the surplus O₂ from the combustion pulse is trapped with Cu. High-temperature conversion of inorganic compounds (and pyrolysis of organic compounds) takes place in carbon-based reactors under helium (He) flow and in the absence of O₂, and it is used to measure O and H isotope ratios. Samples are converted quantitatively to CO and H₂ at temperatures between 1350 °C and 1450 °C. Water is removed by chemical traps magnesium perchlorate (Mg(ClO₄)₂, Sicapent (P₄O₁₀), or Nafion® tubes flushed with helium). The gases produced are then separated by gas chromatography or temperature-controlled traps (purge and trap) and transferred to the IRMS instrument within a clean He flow.

Nowadays, IRMS systems work in continuous flow mode: the sample gases generated by the EA (or another preparation inlet system see Fig. 1) and the corresponding reference gases are carried to the IRMS instrument within a clean He stream in pulses. The traditional IRMS uses a so-called dual inlet valve system. Pure sample gas (obtained offline) and pure reference gas are alternately and iteratively introduced to the ion source via a changeover valve. This method is now used only when samples need to be measured with greater precision and accuracy. For a thorough comparison of the two systems, please refer to Barrie et al. (1996).

Inside the ion source of an IRMS instrument, the gaseous molecules are first ionized, accelerated, and focused and then enter the flight tube, where the ionized molecules are separated into beams by an (electro)magnetic field on the basis of their mass-to-charge ratio (m/z). The intensity of each beam is then measured by ion collectors (Faraday cups) placed in a specific arrangement. The input from each collector is converted into an electric impulse, amplified, and finally integrated and processed. For further info on mass spectrometer hardware be referred to Brand (2004).

Isotope ratios of liquid samples (e.g. H₂O extracted from soil and plant matter) can also be measured after equilibration with CO₂ and/or H₂ gas, which is then separated by gas chromatography or cryogenic trapping and sent to the IRMS system (Fig. 1). The same is valid for gaseous samples, such as atmospheric carbon dioxide (CO₂) and nitrous oxide (N₂O). Because of possible small amounts of the trace gases, a pre-concentration step by cryo-traps might be needed. Nitrous oxide can be analyzed for bulk $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ values; in addition, a measurement of the fragment ion at mass 30 ($^{14}\text{NO}^+$) and 31 ($^{15}\text{NO}^+$) produced in the ion source allows N₂O isotopomer analysis (i.e. intramolecular distribution of ^{15}N in N₂O).

Compound-specific isotope ratio analyses can be performed by coupling gas chromatography (GC) or high-performance liquid chromatography (HPLC) online to an IRMS instrument (Jochmann and Schmidt, 2012).

Recent developments in infrared laser spectroscopy (cavity ring-down spectroscopy, CRDS, and quantum cascade laser absorption spectroscopy, QCLAS; Fig. 1, Li et al., 2013) have enabled less costly measurement of isotope ratios of liquid and gaseous

Fig. 1 Workflow for isotope ratio mass spectrometry (IRMS) measurements. (A) For solid bulk samples (e.g. plants, soil) or purified substances, samples are pretreated and compounds are converted into gases prior to measurements. The carbon reduction is normally performed on glassy carbon under He flow; pyrolysis of N containing organic substances for $\delta^2\text{H}$ analysis is performed in chromium reactors (for more information, see text). In case of coupled HPLC–IRMS for $\delta^{13}\text{C}$ determination, wet oxidation is used. (B) For the analysis of gaseous samples (e.g. CO₂ and N₂O), samples are pre-concentrated prior to IRMS analysis. (C) In the routine isotope ratio analysis of water isotope equilibration with gases is often used: for $\delta^{18}\text{O}$ analysis CO₂, for $\delta^2\text{H}$ analysis H₂-gas in the presence of Pt (platinum). More recently, $\delta^{18}\text{O}$ and $\delta^2\text{H}$ in water can be measured with an online method, using cavity ring-down spectroscopy. Modified after Schmidt H-L, Werner RA, Rossmann A, Mosandl A, and Schreier P (2007) Stable isotope ratio analysis in quality control of flavourings. In: Ziegler H (ed.): Flavourings - Production, Composition, Applications, Regulations. 2nd completely revised edition. Weinheim, D: Wiley-VCH.

samples, and with less preparation. The method, based on specific infrared absorption of different gas molecules, enables continuous measuring of isotope ratios. Although laser spectroscopy does not yet provide the same precision as IRMS, these techniques are becoming increasingly popular, especially for their direct application in field studies.

Natural abundance and labelling approaches

Stable isotope studies are based on the measurement of isotopic natural abundance or deliberately induced changes in isotope abundance (labelling¹). In the latter approach, a compound that is deliberately enriched or depleted in the heavier isotope of an element is introduced into the system being studied. A classic example is the application of ¹⁵N enriched fertilizer to the soil.

The advantage of manipulating isotope abundance is that the targeted transformation or flux, e.g. the N uptake of the plant from a given source, is easily detectable. Such studies also allow processes to be investigated over small temporal and spatial scales ranging from days to a few years, and from microcosms to field experiments. On the other hand, these approaches might be subject to experimental artifacts, such as a non-homogeneous distribution of the tracer throughout a substrate.

Natural abundance studies allow larger temporal and spatial scales to be embraced in biogeochemical cycles (Fig. 2), e.g. soil carbon dynamics over decades (see Section “Natural ¹³C abundance to study SOM dynamics in soil of arable lands”) or phosphorus cycling during pedogenesis (see Section “Oxygen in phosphate to study P cycling”). One of the drawbacks of the natural isotope abundance approach is that, in some cases, the relatively small shifts (few delta units) that can be observed, enable only qualitative assessment and might hamper correct interpretations.

Examples of advantages and disadvantages of the two approaches will be presented in the following sections. Detailed comparisons for specific isotopes are given in Robinson (2001) and Chalk et al. (2017).

Application of isotopes of light elements in soil science

Carbon

In soil science, the C isotope ratio is used as a tracer of plant-C to understand its interaction with the soil matrix and the main pathways of soil organic matter (SOM) accumulation. Paleoenvironmental studies use $\delta^{13}\text{C}$ to evaluate past changes in vegetation

Fig. 2 Schematic representation of C, N, P and S cycles in the soil. A general indication of nutrient pools in soil is given. Abiotic and biotic processes are indicated by arrows, IE: Isotope effect, indicating the presence of known isotopic fractionation of processes. Modified after Janes-Bassett V, Davies J, Rowe Ed C., and Tipping E (2020) Simulating long-term carbon nitrogen and phosphorus biogeochemical cycling in agricultural environments. *Science of The Total Environment*. 714.

¹When the compound is a gas, labelling techniques can be continuous, i.e. continuous exposure of the studied system to the labelled compound or pulsed, i.g. repeated exposure to the labelled compound for short periods of time. An example is provided in Section “Carbon”.

and climate. On the other hand, known changes in vegetation and consequent changes in the $\delta^{13}\text{C}$ of organic matter inputs are used to estimate the turnover time and size of SOM fractions.

Natural ^{13}C abundance to study SOM dynamics in the soil of arable lands

Photosynthesis is the main way how atmospheric CO_2 is captured and transformed into organic compounds. This process occurs with a kinetic isotopic fractionation of C, leading to ^{13}C depletion compared to atmospheric CO_2 , which is different for C_3 and C_4 plants (mean $\delta^{13}\text{C}$ value in C_3 plants is -27‰ , and -13‰ in C_4 plants, Hoefs, 2021). This difference is used to follow the dynamics of plant-C entering the soil through residues left after harvest and their decomposition by soil microorganisms. The use of this technique enables SOM turnover to be followed over medium to long-term scales. For instance, Balesdent and Balabane (1996) grew maize (*Zea mays* L., a C_4 plant) for 4 years in a long-term field experiment that had been previously cultivated with C_3 plants. By following the dynamics of SOM derived from above- and below-ground maize residues, they demonstrated that roots were the major contributor to SOM, while representing only one third of the amount of C inputs to the soil from the residues. These pioneering results stress the importance of roots and associated rhizodeposition mechanisms. They were achieved by following the fate of C_4 plant-C over several years and by using a simple mixing model (Box 2) under the assumptions that the $\delta^{13}\text{C}$ of plant residues is close to that of derived SOM, and that SOM dynamics are close to steady-state.

However, several studies have reported an increase in $\delta^{13}\text{C}$ values with depth in soils under C_3 plants (on average 1–3‰ in the first meter (Balesdent et al., 1993). Different processes were hypothesized to explain this ^{13}C enrichment: (1) roots are enriched in ^{13}C compared to shoots (Werth and Kuzyakov, 2010); (2) isotopic fractionation during microbial respiration leads to an enrichment in ^{13}C during the decomposition process. A recent study concluded that the increase in $\delta^{13}\text{C}$ values with soil depth was due to changes in vegetation $\delta^{13}\text{C}$ over the last 20,000 years (Paul et al., 2020).

Further work based on C_3/C_4 vegetation changes demonstrated that the soil below 30-cm depth (subsoil) contains only 19% of the soil organic carbon (SOC) recently (last 50 years) incorporated, which is mostly concentrated within the first 10 cm of soil. Therefore, cropping seems not to affect the deeper soil horizons greatly in relation to SOM accumulation (> 30 cm, Balesdent et al., 2018).

In cropped ecosystems, natural ^{13}C abundance can also be used to follow the fate of organic fertilizers (waste, digestate or composts as fertilizers, Jamoteau et al., 2021).

Labelling approaches to study SOM in cropped soils

Another way of assessing SOM accumulation and turnover is with ^{13}C labelling of plants in gas-tight growth chambers. The advantage of this technique is the possibility of using a wider range of residues than those from C_4 plants and to apply them to all types of environments regardless of whether C_3 or C_4 plants were present previously. However, these experiments are time consuming and costly, as continuous highly ^{13}C enriched CO_2 injections are required through the whole plant cycle to obtain homogenous labelling of the plant material. An alternative approach is pulse-labelling, where plants are exposed to a $^{13}\text{CO}_2$ flush for short and repeated periods of time. Such methods can be applied in a greenhouse or directly in the field (Leake et al., 2006). More recent methods based on applying dual isotope labelling (^{13}C and ^{15}N) directly onto the leaf surface were reported as being suitable. However, with the leaf surface method the ^{13}C enrichment of the plant tissues remains low ($< 1\%$ atom percent excess or APE, see Table 2) (Putz et al., 2011).

Most studies related to SOM dynamics use labelled crop residues to follow C incorporation into SOM, while those dealing with plant growth or rhizodeposition will need to follow transfer of the tracer from the plants to the soil during the whole life cycle of the plant. The different soil compartments targeted to follow ^{13}C enriched compounds are the rhizosphere, the soil fauna and microorganisms, the SOM and its fractions.

Box 2 Mixing models.

The delta value of a sample (receiver) can be explained by the delta values of the mixing sources (also called endmembers) and their relative contribution (fraction) to the total amount of the element of interest. The equation used is exemplified here for ^{15}N and the simplest case of two contributing sources:

$$\delta^{15}\text{N}_{\text{sample}} = \delta^{15}\text{N}_{\text{sourceA}} * f + \delta^{15}\text{N}_{\text{sourceB}} * (1 - f) \quad (1)$$

where $\delta^{15}\text{N}_{\text{sample}}$ is the delta value of the sample, $\delta^{15}\text{N}_{\text{sourceA/B}}$ are the delta values of the two distinct sources A and B, and f and $1 - f$ are the relative contributions of the two sources.

Rearranging equation 1, the fraction f can be calculated:

$$f = \frac{\delta^{15}\text{N}_{\text{sample}} - \delta^{15}\text{N}_{\text{sourceB}}}{\delta^{15}\text{N}_{\text{sourceA}} - \delta^{15}\text{N}_{\text{sourceB}}} \quad (2)$$

Note that Equation 2 is sometimes written with the numerator and denominator multiplied by -1 , as in the example of the N in a legume derived from atmospheric N_2 (PNdfa, see Section “The use of ^{15}N enriched fertilizers”).

To calculate the mass of N derived from one source in the sample, the total mass of N in the sample must be known. For example, for source A we have:

$$\text{mass}_{\text{sourceA}} = f * \text{mass}_{\text{sample}} \quad (3)$$

- Use of stable isotopes to follow C dynamics from living plants

The amount and quality of C entering the soil through rhizodeposition is still controversial. The interaction between the rhizosphere leads to an increase or decrease of SOC concentration and is termed rhizosphere priming effect. This process could accelerate SOC mineralization by 59% compared to unplanted soil (Huo et al., 2017). The rhizosphere priming effect cannot be studied without isotopes, either stable or radioactive (^{14}C). To distinguish the origin and fate of rhizosphere C, ^{13}C labelling of plants is needed, although several studies use the addition of ^{13}C labelled compounds to mimic root exudates.

- Use of stable isotopes to follow C dynamics from litter residues

Residues enriched with ^{13}C are mostly from plants growing under ^{13}C enriched CO_2 . The level of enrichment ranges around 3 to 5% APE. However, specific studies require strongly labelled residues (i.e. about 99% APE). This is the case of DNA stable isotope probing (DNA-SIP) which, in combination with metagenomics, is dedicated to the identification of the soil microorganism functions in the environment (Bernard et al., 2007).

Plants residues are the main source of organic matter entering the soil. Microbial products resulting from the assimilation of labile components in residues by microorganisms (i.e. microbial immobilization) and microbial turnover were recently shown to contribute significantly to the accumulation of SOM (Cotrufo et al., 2015). These results challenge previous studies, which contend that chemical recalcitrance of residues was the main driver of the rate of decomposition and SOM formation. The study by Cotrufo and collaborators used ^{13}C labelled residues to follow the incorporation of C in active soil microbial biomass (by ^{13}C -PLFA, phospholipid fatty acid analyses) over several years and in SOM fractions for different soil layers (from 0 to 20 cm depth).

The ^{13}C labelled substrates (residues, glucose or other organic compounds) are added to soil in incubation experiments to study microbial response to C addition. Such approaches aim at understanding microbial processes such as stoichiometric constraints (Heuck et al., 2015), enzyme efficiency (Fanin and Bertrand, 2016), carbon use efficiency (Sauvadet et al., 2018) and priming effect (Perveen et al., 2019). In such applications, ^{13}C labelled substrates are an asset for a better understanding of microbial functions and their impact on the environment.

Nitrogen

Human alterations of the global N cycle have dramatically increased emissions of reactive N compounds into terrestrial and aquatic systems and into the atmosphere. Agricultural production plays a key role in these changes because food production depends on the use of reactive N. The ^{15}N enrichment and natural abundance methods have greatly advanced the understanding of N fluxes and dynamics in agricultural systems (arable crops and grassland), which is required to reach more efficient fertilizer N use with fewer losses to the environment.

The use of ^{15}N enriched fertilizers

The use of ^{15}N enriched mineral or organic fertilizers such as animal manures and legume green manures allows fertilizer N to be tracked over time and across different compartments. Often less than half of fertilizer N is taken up by the crops (Douxchamps et al., 2011; Frick et al., 2022). With ^{15}N enriched fertilizers, the fate of fertilizer N not taken up by crops can be tracked into soil N pools and N losses can be quantified. The basic requirement for tracking is that the fertilizer N is homogeneously labelled with ^{15}N . Homogeneity of ^{15}N labelling is usually not a concern for pure, water soluble synthetic N compounds such as urea or ammonium nitrate, which can be either purchased at the required level of ^{15}N enrichment, or produced in a laboratory. The production of homogeneously labelled organic fertilizers is much more challenging. For instance, the production of ^{15}N labelled animal manure requires several days of feeding animal(s) with ^{15}N labelled forage, analysis of the ^{15}N enrichment of urine and feces collected at different times since the start of feeding, and checking on the homogeneity of ^{15}N labelling, e.g. with physicochemical fractionation of fecal N (Frick et al., 2022). The ^{15}N labelled legume residues for green manures have been produced under field and greenhouse conditions (Douxchamps et al., 2011; Traoré et al., 2020), but for mature plant material the ^{15}N enrichment may differ between plant parts, e.g. leaves and stems. The proportion of N in the receiver pool derived from the labelled fertilizer is: $\text{Ndff} = \frac{^{15}\text{N excess}_{\text{receiver}}}{^{15}\text{N excess}_{\text{source}}}$, with excess being the APE as defined in Table 2.

When the size of the receiving pool is known, recovery of the fertilizer in that pool can be calculated. Use of ^{15}N enriched fertilizers has provided information on the:

- recovery of mineral and organic fertilizer N in crops in the year of application and during the following years, delivering information on the residual fertilizer value (Douxchamps et al., 2011; Frick et al., 2022);
- quantification of fertilizer N remaining in the soil over years (see compilation in Smith and Chalk, 2018);
- incorporation of fertilizer N into soil N pools, such as mineral and microbial N (see for example Frick et al., 2022) and into soil aggregate fractions (Bosshard et al., 2008);
- losses of fertilizer N by leaching, denitrification and ammonia volatilization (see for example Thomsen et al., 1997);
- symbiotic N_2 fixation by legumes, through the use of the residual ^{15}N enrichment in soil (Oberson et al., 2007).

Gross N fluxes in soil, namely ammonification and nitrification, have been quantified using ^{15}N pool dilution. This approach has elucidated the significance of gross N fluxes compared to net N mineralization (Braun et al., 2018 and references therein), and their

response to management intervention such as soil tillage or the integration of grasses with nitrification inhibition capacity (Teutschnerová et al., 2022).

The ^{15}N labelling of legumes has been used to estimate their belowground N input (Hammehle et al., 2018) and the transfer of legume N to associated non-fixing plants (Pirhofer-Walzl et al., 2012).

Because of high ^{15}N tracer costs, field applications of ^{15}N enrichment are limited to microplot scales with a maximum of few m^2 per unit.

The use of ^{15}N at natural abundance

The work with ^{15}N natural abundance bases on natural ^{15}N enrichment usually encountered in soils ($\delta^{15}\text{N}$ of 2‰ to 15‰) relative to atmospheric N_2 ($\delta^{15}\text{N}$ of 0‰). This difference has frequently been used to obtain the proportion of N in legumes derived from atmospheric N_2 by symbiotic fixation (see compilation in Chalk et al., 2016).

The great advantage of ^{15}N natural abundance work is that it is not limited in space, and no methodological intervention is needed in the field. However, potential bias induced by isotopic fractionation has to be carefully considered (Robinson, 2001 and references therein), and here it is explained using symbiotic N_2 fixation in legume shoots as an example. Determination of the proportion of N in a legume derived from atmospheric N_2 (PNdfa) is based on the two pools mixing model (mixing of two sources, and a sink or receiver, see Box 2). The equation is:

$$\text{PNdfa} = \frac{\delta^{15}\text{N}_{\text{soil}} - \delta^{15}\text{N}_{\text{legume}}}{\delta^{15}\text{N}_{\text{soil}} - \delta^{15}\text{N}_{\text{atm}}} \quad (4)$$

where $\delta^{15}\text{N}_{\text{soil}}$ is the $\delta^{15}\text{N}$ of a non-fixing reference plant reflecting the $\delta^{15}\text{N}$ of the soil available N pool (first source); $\delta^{15}\text{N}_{\text{atm}}$ is the $\delta^{15}\text{N}$ of the legume relying solely on atmospheric N_2 (second source, in literature often called B), $\delta^{15}\text{N}_{\text{legume}}$ is the $\delta^{15}\text{N}$ of the legume (receiver) (Shearer and Kohl, 1986). This implies that the reference plant takes up N in a similar temporal and spatial pattern to that of the legume, and with the same isotopic fractionation involved. Sampling of different reference plants, from various species, all growing near to the legume, and under the same management as the legume studied, helps to reduce related uncertainty (Obersen et al., 2013). The isotopic fractionation taking place during N_2 fixation and transport of fixed N from nodules to legume shoots is accounted for by the $\delta^{15}\text{N}_{\text{atm}}$ value, which is usually depleted in ^{15}N compared to atmospheric N_2 (e.g., -0.08‰ to -2.6‰ , Büchi et al., 2015). The same principle has been applied to derive the transfer of legume N to associated non fixing plants (Obersen et al., 2013).

Fertilizers differ in their $\delta^{15}\text{N}$ values. The $\delta^{15}\text{N}$ of synthetic fertilizer usually ranges from -3‰ to $+3\text{‰}$, for livestock manure from $+3\text{‰}$ to $+14\text{‰}$, and for composted manure from $+8\text{‰}$ to $+20\text{‰}$ (range indicating 90% of the respective fertilizers, Choi et al., 2017). These differences are used to derive the proportion of fertilizer N derived in the crop (Manandhar et al., 2022). In all these applications, it is necessary to check carefully that the $\delta^{15}\text{N}$ values of the two sources are clearly distinct, and that they account for isotopic fractionation during the transfer of N from these sources to the receiver.

The $\delta^{15}\text{N}$ value of plant shoot tissue has also been used to identify the form of soil N taken up (e.g., preference of ammonium over nitrate, Kahmen et al., 2008). It was the original means of detecting biological N fixation in tropical grasses such as sugar cane (*Saccharum officinarum* L.) or *Urochloa* spp. grasses (Villegas et al., 2020).

To reduce N losses from agricultural fields to other environmental compartments, future studies should explore the mechanisms of N retention in soil at the same time as supplying mineral N to plants. Because the nitrogen cycle is coupled with the carbon cycle, multi-element studies using multiple isotopes will become increasingly relevant.

Oxygen

Oxygen isotopes in the soil water–plant–atmosphere continuum

Stable isotopes in soil water (^2H and ^{18}O) have been used for decades to assess flows in the unsaturated zone and to understand plant water uptake and evapotranspiration patterns. Here we provide some general aspects of O isotopes in the soil–plant–atmosphere continuum. The reader can refer to Gat (2010) and Sprenger et al. (2016) for in-depth accounts.

Precipitation water entering the soil may partially evaporate and the water remaining in the soil will become enriched in heavy isotopes through kinetic isotopic fractionation. Uptake by plants does not produce significant isotopic fractionation. In contrast, leaf water might be considerably enriched in ^{18}O (and ^2H) relative to soil water due to isotopic fractionation during transpiration (Yakir and da Sternberg, 2000). Evapotranspiration can be partitioned by applying mixing models (see Box 2) that combine the isotopic composition of atmospheric water, the transpired water and evaporated soil water (Sprenger et al., 2016 and references therein).

Mixing models are also applied to study the depth or distribution of root water uptake, i.e. by comparing the isotopic composition of the xylem water with the isotopic composition of possible water sources (rainfall, pore water in upper and deeper soil horizons).

In addition to natural isotope abundance, application of isotopic tracers (water artificially enriched in the heavier isotopologs) has also been used to assess sources of water uptake by plants and processes such as the hydraulic lift. For instance, Meunier et al. (2018) used ^{18}O enriched water to label the soil water in deep soil layers and subsequently observed an ^{18}O enrichment of water in

the upper soil layers. They explained these differences by the hydraulic lift operated by the roots of *Lolium multiflorum* (Lam.), Italian ryegrass.

In the plant, carbon dioxide, water and dioxygen (O_2) are the primary sources of O in organic compounds (Schmidt et al., 2001). In contrast to O atoms in hydroxyl groups, O in carbonyl groups of aldehydes and ketones are known to be easily exchangeable with surrounding H_2O molecules (da Silveira Lobo O'Reilly Sternberg and DeNiro, 1983). This leads to an ^{18}O equilibrium enrichment of these functional groups relative to water. Oxygen isotope exchange of intermediates during biosynthesis leads to an ^{18}O enrichment of $+27\text{‰} \pm 3\text{‰}$ of cellulose relative to leaf water (da Silveira Lobo Sternberg, 1989 and literature cited therein). The oxygen isotopic composition of plant carbohydrates is therefore related to that of the water available during biosynthesis and can be used to assess the physiology of plants and obtain information on (paleo)climate (Gessler et al., 2014).

Oxygen in phosphate to study P cycling

In the past two decades, researchers have increasingly used the isotopic composition of O in phosphate ($\delta^{18}O_P$) to study phosphorus cycling in soils, sediments and the soil–plant system.

Phosphorus (P) in the environment is most often associated to four O atoms (PO_4^{3-} , hereafter phosphate), whether in its inorganic or organic forms. The P—O bond is only cleaved by biological processes at temperatures and pressures commonly found on the Earth's surface. In such circumstances, the $\delta^{18}O_P$ retains a trace of the biological processes that the phosphate molecule went through until another biological process intervenes. In the absence of or under limited biological activity, $\delta^{18}O_P$ remains essentially unchanged and can be used with some caveats as a tracer of the origins of P, such as in studies of P transfer from land to surface waters (see as an example Pistocchi et al., 2017).

Larsen et al. (1989) first demonstrated the effect of soil biological activity on the $\delta^{18}O_P$ of soil phosphate by applying $KH_2P^{18}O_4$ to soil treated or untreated with a biocide. Half of the original ^{18}O enrichment was lost in soil phosphate after 3 months of incubation of the biologically active soil due to the cycling of P by soil microorganisms, whereas no label change was observed in the treated soils.

The biological processes causing cleavage of the P—O bond are important enzyme reactions such as the intra- and extra-cellular organic P mineralization through phosphoesterases and the intracellular reactions catalyzed by pyrophosphatase (PPase). The PPase-catalyzed reactions produce an equilibrium isotopic fractionation and complete exchange of the four O atoms of the phosphate with the O atoms of the water (Cohn, 1958). Hence, this equilibrium isotopic fractionation is considered a marker of P cell metabolism. In contrast, the mineralization of organic P compounds by phosphoesterases implies the exchange of one or two O atoms of the phosphate moiety with the surrounding water. The kinetic isotopic fractionation associated with this process is known for a small number of enzymes (ϵ between $+10\text{‰}$ and -20‰ , Liang and Blake, 2006; von Sperber et al., 2015).

The $\delta^{18}O_P$ at natural abundance has been used successfully in chronosequence studies to show how P in primary soil minerals was biologically cycled during pedogenesis (Tamburini et al., 2012; Frkova et al., 2022) or along a weathering gradient in Hawaii (Helfenstein et al., 2018). These studies showed that under conditions that are favorable to microbial activity (e.g. soil humidity), primary P is biologically cycled after a few hundred years, whereas under arid or semi-arid conditions the biological recycling of primary P can take thousands of years.

Experiments with ^{18}O -enriched compounds (either water or phosphate) have been used to infer the prevalent biological processes affecting P in soil solution, the main pool available to plants (Siegenthaler et al., 2020). Pistocchi et al. (2020) have shown that in a P-limited soil horizon, the available P had a $\delta^{18}O_P$ value that was close to that expected from the mineralization of organic P, thus this process was the main contributor to the available P pool. Labelled phosphate compounds have also been used in the field to follow the fate of P fertilizers into soil P pools (Joshi et al., 2016). Incubation experiments with doubly labelled substrate seem promising to study C and P cycles simultaneously in soils (Gross and Angert, 2017).

Oxygen in nitrate and sulfate

The isotope composition of oxygen in nitrate ($\delta^{18}O_{NO_3}$) is used to study nitrate sources and its fate (e.g. nitrate leaching) in terrestrial ecosystems, mostly under natural abundance. The soil nitrate $\delta^{18}O_{NO_3}$ (and $\delta^{15}N_{NO_3}$) may reflect 'natural conditions' or the effects of various anthropogenic impacts such as increased atmospheric N deposition and acidification. Nitrate from atmospheric deposition is strongly enriched in ^{18}O ($\delta^{18}O_{NO_3} > 60\text{‰}$). Synthetic fertilizers, where oxygen is derived from atmospheric O_2 (ca. $+23.5\text{‰}$), have $\delta^{18}O_{NO_3}$ values ranging from $+17\text{‰}$ to $+25\text{‰}$ (Kendall et al., 2007).

Among biological processes, denitrification leaves the residual nitrate pool relatively enriched in both ^{18}O and ^{15}N , with a constant ratio varying between 1:1 and 1:2. In contrast, the isotope effects that affect O and N during nitrification are unrelated because the sources of O and N atoms are different. During nitrification, the O atoms come from water and O_2 , thus the $\delta^{18}O_{NO_3}$ of the nitrate produced reflects the isotopic composition of both sources. Nitrate from nitrification is expected to have $\delta^{18}O_{NO_3}$ values in the range of -10‰ to $+10\text{‰}$. Uncertainties remain about isotopic fractionation associated with O incorporation from O_2 or water, and the degree of equilibrium oxygen isotope exchange with water during reversible steps of nitrification (Kendall et al., 2007; Kool et al., 2011).

The coupled pattern of N and O isotope effects associated with nitrate-consuming processes, such as denitrification and plant uptake, help to constrain the interpretation of isotope data when mixing of multiple nitrate sources can be neglected, such as in non fertilized ecosystems. The deviation from the coupled 1:1 pattern of the $\delta^{18}O_{NO_3}$ and $\delta^{15}N_{NO_3}$ can then be interpreted as the effect of processes inducing unrelated N and O isotope effects, like nitrification.

With the natural isotope abundance approach, the amount of nitrate derived from atmospheric deposition that is leached from soils can be quantified. Recently, Fang et al. (2015) coupled $\delta^{17}\text{O}$, which is an unambiguous tracer of atmospheric nitrate, to $\delta^{18}\text{O}_{\text{NO}_3}$ and $\delta^{15}\text{N}_{\text{NO}_3}$ and successfully quantified gross rates of nitrification and denitrification in a range of forest ecosystems.

Compared to oxygen isotope composition in nitrate, $\delta^{18}\text{O}_{\text{SO}_4}$ is less used in soil studies. As for phosphate, oxygen in sulfate (SO_4^{2-}) does not exchange easily with O atoms in water under common temperature and pressure conditions of terrestrial ecosystems. Sorption to soil particles does not induce isotopic fractionation. Therefore, the $\delta^{18}\text{O}_{\text{SO}_4}$ can be used to infer the extent of biological cycling affecting soil sulfate.

Krouse et al. (1996) observed that $\delta^{18}\text{O}_{\text{SO}_4}$ in aerated forest subsoil with negligible S inputs from parent material is smaller by several units than that in superficial pore water originating from rainwater, while $\delta^{34}\text{S}_{\text{SO}_4}$ is relatively similar. These differences are thought to be the result of S cycling through the biota (plants or microorganisms) by assimilatory reduction and subsequent mineralization of carbon-bound S to sulfate. Mineralization induces the incorporation of 45–75% O atoms into the newly formed sulfate from soil water and atmospheric O_2 (the majority of O incorporation is from water). An isotopic fractionation described by a negative ϵ ranging from -4.3‰ to -11.4‰ is associated with O incorporation from O_2 . Usually, $\delta^{18}\text{O}_{\text{SO}_4}$ values below 5‰ are expected for newly mineralized sulfate (Krouse et al., 1996 and references therein).

Under reducing conditions, such as in peatlands, the $\delta^{18}\text{O}_{\text{SO}_4}$ measured along the soil profile might indicate the extent and depth of dissimilatory sulfate reduction by anaerobic bacteria, which leaves the residual sulfate enriched in heavy isotopes (both O and S) (Novák et al., 2005).

Small values of $\delta^{18}\text{O}_{\text{SO}_4}$ in soil sulfate can also derive from parent material containing reduced S (e.g. pyrite), for example in glacial tills (-5‰ to -20‰ , Krouse et al., 1996 and references therein). On the other hand, sulfate from primary evaporites generally has larger $\delta^{34}\text{S}_{\text{SO}_4}$ and $\delta^{18}\text{O}_{\text{SO}_4}$ ($+9\text{‰}$ to $+18\text{‰}$) values than sulfate derived from oxidation of inorganic or organic S compounds and subsequent reprecipitation (secondary sulfates). Therefore, the study of both S and O isotopes in sulfate provides unique information on sulfate cycling in soils and on its origin from primary or secondary minerals.

As for nitrate, the $\delta^{17}\text{O}$ of sulfate can be used to assess the relative contribution of atmospheric sulfate to terrestrial inputs (Kendall et al., 2007).

Sulfur

Sulfur (S) has four stable isotopes (Table 1). Among these, ^{34}S is the only one used in soil studies, but far less than the stable isotopes of C and N. The majority of earlier studies concern forest ecosystems and understanding of the effects of anthropogenic S emissions on S cycling (Krouse et al., 1996). In recent years, S deficiencies in crops have been increasingly identified because of the worldwide reduction in industrial S emissions and the increase in demand for S by crops with increasing yields. Several recent studies address S dynamics and fertilization in agroecosystems with the use of stable isotopes (Chalk et al., 2017 and references therein).

Atmospheric $\delta^{34}\text{S}$ values are in the range of -5‰ to $+25\text{‰}$. Soil sulfur displays a very large range of $\delta^{34}\text{S}$ values (-30‰ to $+30\text{‰}$), while soil sulfate has a somewhat narrower range (-25‰ to $+20\text{‰}$; Chalk et al., 2017).

Dissimilatory sulfate reduction by microorganisms is known to produce the strongest isotopic fractionation, producing ^{34}S -depleted sulfide (S^{2-}), although the magnitude of the isotope fractionation factor is not known with precision. Isotopic fractionation associated with microbiological sulfide oxidation is less (ϵ up to $+12.5\text{‰}$). Even smaller isotopic fractionations are associated with S mineralization ($<+2\text{‰}$) and plant sulfate uptake ($<\pm 1\text{‰}$) (Chalk et al., 2017; Hoefs, 2021).

Measurements of $\delta^{34}\text{S}$ natural abundance in agroecosystems have been used to discriminate between sources (e.g. atmospheric deposition and fertilizers) that contribute to plant S uptake or to soil S. The difference in $\delta^{34}\text{S}$ between soil and anthropogenic S provides the basis to estimate the relative contribution of S from different sources. In long-term experiments, an increasing and decreasing trend of S concentrations in soil and crops followed the increase and decrease of anthropogenic S emissions during the last century. This trend in S concentrations was mirrored by the $\delta^{34}\text{S}$ values in soil S, which were highest in 1860, they were at a minimum in 1972, and then increased again later. This trend relates to the use of coal, the source of most anthropogenic S emissions, which was depleted in ^{34}S (Chalk et al., 2017).

Analogous to studies with ^{15}N enriched fertilizers, ^{34}S enriched (or depleted) fertilizers have been used to estimate S fertilizer efficiency, mostly in pot studies (Chalk et al., 2017).

Current trends and future developments

Multi-isotope and multi-tracer approaches that also integrate complementary analytical techniques are increasingly used in soil studies (see for example Helfenstein et al., 2018).

Compound-specific isotope probing has opened avenues for tracking pathways and components of the N and C cycles, such as decomposition, assimilation, and de novo synthesis of molecules and microorganisms involved obtained by ^{15}N -DNA probing, ^{13}C - and ^{18}O -DNA and RNA probing, and ^{13}C -PLFA (phospholipid-derived fatty acid) (examples of such approaches are given in Jochmann and Schmidt, 2012). However, these applications are still limited to the laboratory scale.

Such approaches together with analytical advances will probably enable an increasingly wide range of questions to be addressed regarding the cycling and sources of key elements of life in soil and the environment. Here, we report some promising examples and recent technical advances.

Site-specific ^{15}N analyses and clumped isotopes to study N_2O emissions

The biogeochemical cycle of N in soil systems has been studied by determining the isotopic composition of emitted N_2O and quantifying its source and sink processes (Decock and Six, 2013). The studies mostly focus on the four most abundant N_2O isotopocules: $^{14}\text{N}^{14}\text{N}^{16}\text{O}$, and singly substituted isotopocules $^{14}\text{N}^{15}\text{N}^{16}\text{O}$, $^{15}\text{N}^{14}\text{N}^{16}\text{O}$, and $^{14}\text{N}^{14}\text{N}^{18}\text{O}$, with resulting delta values $\delta^{15}\text{N}^{\text{bulk}}$ (the average abundance of $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ and $^{15}\text{N}^{14}\text{N}^{16}\text{O}$) and $\delta^{18}\text{O}$ ($^{14}\text{N}^{14}\text{N}^{18}\text{O}$). A difference between the abundance of the two isotopomers $^{14}\text{N}^{15}\text{N}^{16}\text{O}$ and $^{15}\text{N}^{14}\text{N}^{16}\text{O}$, denoted as ^{15}N site preference (SP), has proved to be a useful tracer for distinguishing different microbial sources (denitrification vs nitrification, Sutka et al., 2006). However, interpretation of N_2O isotopic data from large, plot-scale studies is demanding because N_2O emissions and their isotopic signatures are influenced by many factors, e.g. soil moisture, soil pH, occurrence of large emission events in time (so called 'hot moments') or from particular locations ('hot spots'), or availability of reaction substrates.

Isotopic analysis of N_2O has undergone considerable development in recent years. Classical IRMS has been accompanied by methods based on laser spectroscopy (see Section "Analytical methods") that can be applied directly in the field and supply real-time data. Both methods, however, require a preconcentration technique for focusing the analyte into a smaller volume and removing potential interfering compounds (CO_2 , CH_4 , etc.).

A promising new tracer that will shed more light on N dynamics is the abundance of multiply substituted N_2O isotopocules, so called 'clumped isotopes' ($^{14}\text{N}^{15}\text{N}^{18}\text{O}$, $^{15}\text{N}^{14}\text{N}^{18}\text{O}$, $^{15}\text{N}^{15}\text{N}^{16}\text{O}$, Ostrom and Ostrom, 2017). An analysis of clumped N_2O is already available through new IRMS and laser spectroscopy methods, but has been applied so far only to laboratory-based experiments (N_2O produced by denitrification and degraded by UV photolysis, Kantnerová et al., 2020a; Kantnerová et al., 2020b). For clumped isotope analysis in soil-emitted N_2O , the current preconcentration techniques need to be modified to process larger amounts of N_2O that the new methods currently require.

Isotopic analysis of oxyanions, bulk isotopes composition of total dissolved C and N and of soil carbon pools

Until recently, it has not been possible to analyze oxyanions of the key elements of life directly, e.g. nitrate, phosphate, or sulfate. Prior to the analysis, the analyte has to be converted to a low-molecular weight gas (e.g. for nitrate to N_2O or to N_2 and O_2), which might lead to a loss of the original isotopic information. Over the last 5 years, a new methodology for stable isotope analysis has been under development, using Fourier-transform mass spectrometry with Orbitrap™ mass analyzers (Eiler et al., 2017). Its sample introduction technique does not destroy the oxyanions, therefore they can be analyzed directly and the original information is retained. In addition, because of its sensitivity, the method makes isotope clumping in the oxyanions analytically accessible. So far, it has been shown that the technique can be applied to samples of nitrate, sulfate, phosphate, and even acetate (Mueller et al., 2022 and references therein).

Tools are now available to analyze simultaneously the bulk isotopic composition of total dissolved C and N in liquid samples without offline sample preparation, which was previously impossible. This is achieved by coupling a modified high temperature combustion TOC (total organic carbon) analyzer to an IRMS system (Federherr et al., 2016). Similarly, a TOC analyzer coupled to a Picarro $\delta^{13}\text{C}$ - CO_2 analyzer enables the total dissolved inorganic and organic C isotopes to be measured in liquid samples.

To characterize different soil organic and inorganic C fractions, a novel approach has recently been developed that exploits their distinctive thermal stability (Natali et al., 2018). The thermally based separation is achieved through an automated elemental analyzer (EA), which is coupled with an IRMS. This enables the isotopic analysis of soil organic C pools and soil inorganic C, and avoids the isotopic fractionation of SOM potentially induced by the acid pre-treatment commonly used to strip inorganic C. This analytical approach provides a more in-depth characterization of the composition of SOM fractions and their evolution with physicochemical and biological processes.

Such technical advances will provide so far unobtainable isotope information that can be used to understand further the biogeochemical cycling of many elements and simplify current analytical procedures.

Abstract

Radioactive isotopes have been applied in soil science contexts for over 70 years. Their use in soil science is largely based on the isotopic dilution principle. A range of soil pools and processes can be quantified with the use of radioactive isotopes, which would otherwise be difficult to do based on conventional approaches alone. This chapter covers the basic principles and main approaches of using radioactive isotopes in soil science applications. Their continued use will be essential in helping to address major challenges of global concern (e.g., food security and climate change).

Key points

- Radioactive isotopes are an important tool to study pools and processes in soil.
- Approaches in soil science contexts are largely based on the isotopic dilution principle.
- Several methodological factors and assumptions need to be met when applying the isotopic dilution principle.
- Future research will benefit from a holistic view involving multiple isotopes (e.g., C-14, N-15, and P-33) and analytical techniques (e.g., chromatographic and spectroscopic approaches).

Introduction

The soil environment is critical to all life on Earth. Soil is an important source of nutrients for plants and microorganisms, contains a myriad of microorganisms that degrade organic residues and biowastes, and is a vital reservoir of carbon (C) as organic matter. Furthermore, understanding the quantity and turnover of nutrients in soils can lead to greater food security and improved water quality of aquatic or marine ecosystems. Consequently, soil is a key area of concern and new insights on nutrient pools and processes in soil will help address major global challenges such as climate change and food security.

Crop production largely relies on the supply of essential plant nutrients from the soil environment (Frossard et al., 2000). However, soils are often deficient in these nutrients for optimum crop growth (McLaughlin et al., 2011). In contrast, some soils contain an excess of nutrients possibly due to overfertilization which represents a potential risk of transfer to aquatic or marine ecosystems. An important aspect of sustainable crop production involves understanding the quantity and transfer of nutrients in soil. However, new insight on nutrient pools and processes in soil has been limited due to three main factors (Frossard et al., 2011). This includes the difficulty to: (1) distinguish the relative importance of various abiotic and biotic processes in complex systems; (2) assess small changes in nutrient pools compared to that of the total pool of nutrients in soil (differences can be at least one order of magnitude), and; (3) investigate changes in nutrient transfer that can occur at differing timescales (e.g., seconds to years). Addressing these difficulties in agroecosystems can lead to improved crop recovery of fertilizer, reduced fertilizer inputs, and less nutrient transfer to aquatic or marine ecosystems (McLaughlin et al., 2011).

The addition of mineral fertilizers and organic amendments to soils has been an important strategy to improve crop and pasture production. However, direct information on the crop recovery of nutrients released from mineral fertilizers and organic amendments remains limited (McLaughlin et al., 2011). There is also limited information on how agronomic management strategies improve the crop recovery of nutrients from mineral fertilizers and organic amendments. Various approaches have been proposed to track the fate of nutrients from mineral fertilizers and organic amendments in the soil-plant system (Johnston et al., 2014). However, approaches that use radioactive isotopes are perhaps the most important and informative (McLaughlin et al., 2011).

For over 70 years, radioactive isotopes have been an important tool in understanding nutrient pools in soil and their dynamics, and to track the fate of nutrients in the soil-plant system (Frossard et al., 2011). This chapter examines the basic principles and some of the main applications of using radioactive isotopes to probe nutrient pools and their transformation in soil, and as a tracer to assess the fate of fertilizers in soil-plant systems.

Basic principles of radioactive isotopes

At a foundational level, all matter in soil is comprised of atoms from a diverse array of elements. These elements consist of atoms that differ in their atomic number (symbol 'Z'), i.e., the number of protons. For example, all C atoms have six protons ($Z = 6$) whereas all nitrogen (N) atoms have seven protons ($Z = 7$) in the nucleus. Furthermore, nearly all naturally occurring elements comprise multiple isotopes. Isotopes of a particular element consist of atoms that have the same atomic number (protons), but differ in their mass number (symbol 'A'), i.e., the number of protons and neutrons. For example, two important isotopes of N include N-14 with seven protons and seven neutrons ($A = 14$) and N-15 with seven protons and eight neutrons ($A = 15$) in the nucleus. Isotopes of a given element will all exhibit the same chemical behavior, but may undergo various chemical, biological, physical processes at slightly different rates because of small differences in mass. The relative abundance of these naturally occurring isotopes differs among all elements. For example, all naturally occurring samples will consist of N-14 at 99.6% abundance and N-15 at 0.4% abundance.

There are two main classes of isotopes, i.e., 'stable' and 'unstable' isotopes. Stable isotopes refer to atoms with a nucleus of stable configuration which remain constant with time, and do not undergo radioactive decay. In contrast, unstable (or radioactive) isotopes refer to atoms with a nucleus of unstable configuration which will transform over time, and will undergo radioactive decay until a stable configuration is reached. For example, the radioactive isotope of C-14 ($Z = 6$ and $A = 14$) decays to the stable isotope of N-14 ($Z = 7$ and $A = 14$). The process of radioactive decay involves the emission of (radiation) energy.

A major concern with radioactive decay is the emission of ionizing radiation, which potentially has enough energy to remove electrons from atoms and cause the atom to be charged (or ionized). There are several different types of radioactive decay with varying levels of ionizing 'power' and penetration depth. Some important types include: (1) α , alpha particles (helium particles); (2) β^- , beta particles (negatively charged electrons); (3) β^+ , positrons (positively charged electrons), and; (4) γ , gamma rays (photons). Alpha particles are strongly ionizing due to their charge and mass, but their penetration depth is weak and can be easily shielded (e.g., air gap of a few centimeters, skin, or a sheet of paper). Beta particles (and positrons) are moderately ionizing due to their small mass, but can penetrate to greater depths than alpha particles. Beta particles require moderate shielding (e.g., 10 mm thick sheets of acrylic). Gamma rays are of high energy but have no mass or charge, and are the least ionizing form of radiation. However, gamma rays also have the greatest penetration depth and require the most shielding (e.g., thick lead bricks).

All radioactive decay processes follow first-order kinetics, but the rates of decay differ among isotopes. The law of radioactive decay describes the change in nuclei with time (Eq. 1). The 'half-life' ($t_{1/2}$) of a radioactive isotope can then be determined, which refers to the time needed for a given quantity of an unstable isotope to reduce by half. The half-life of a radioactive isotope can vary widely among isotopes (e.g., seconds to millions of years), and is calculated using Eq. (2).

$$N_t = N_0 \times e^{-\lambda t} \quad (1)$$

where N_t refers to the number of nuclei after a given time, t , N_0 refers to the number of nuclei at the start ($t = 0$), and λ refers to the decay constant.

$$t_{1/2} = \frac{0.693}{\lambda} \quad (2)$$

where $t_{1/2}$ refers to the time needed for a given quantity of an unstable isotope to reduce by half (e.g., minutes, days, or years), and λ refers to the decay constant.

There are over 3000 known radioactive isotopes, but the vast majority are made artificially and have half-lives less than 60 min. This makes them impractical for use in most soil science contexts. Furthermore, many radioactive isotopes are not commercially available, but some could potentially be produced in nuclear reactors or cyclotrons for research purposes. Table 1 shows some important radioactive isotopes used in soil science applications.

Units of radioactivity

The becquerel (Bq) is the international unit (SI unit) of radioactivity, which is defined as one nuclear disintegration per second (DPS) (FAO/IAEA, 2016). The non-SI unit of the curie (Ci) is still widely reported in some countries and recently defined as 1 Ci equals 3.7×10^{10} Bq, based on the number of DPS in 1 gram of radium.

Table 1 Some common radioactive isotopes used in soil science contexts.

Parent isotope (radioactive)	Daughter isotope (stable)	Half-life	Main type(s) of energy emitted	Maximum decay energy (MeV)
C-14	N-14	5700.00 y	Beta	0.16
K-42	Ca-42	12.36 h	Beta	3.53
P-32	S-32	14.27 d	Beta	1.71
P-33	S-33	25.35 d	Beta	0.25
S-35	Cl-35	87.37 d	Beta	0.17
Zn-65	Cu-65	243.93 d	Beta (Positron) + Gamma	1.35

Data sourced from the IAEA (2022).

Detection and measures of radioactivity

For most soil science applications, activities in the kilobecquerels (kBq) or megabecquerels (MBq) range will be required. Some of the factors that need to be considered include: (1) the safety regulations on the use, handling, transport, and disposal of radioactive isotopes; (2) the half-life of the radioactive isotope; (3) the analytical method and experimental approach; (4) soil properties, target element pool, or plant selection; (5) the duration of the experiment; (6) the estimated recovery of the radioactive isotope in the sample for measurement, and; (7) the available budget.

Measures of radioactivity from beta emitters primarily occur in solution using a liquid scintillation counter (LSC) (FAO/IAEA, 2016). This typically involves a known aliquot of the unknown solution in a scintillation vial and a known volume of scintillation cocktail, which converts radiation energy to photons of light and is detected by a photomultiplier in the LSC. Measures of radioactivity by the LSC in scintillation vials are generally given as counts per minute (CPM), which is proportional to the concentration of the radioactive isotope in the sample. However, the transfer of radiation energy into photons of light can be reduced due to the inefficient transfer of energy to the solvent and scintillator molecules (termed 'quenching') (Blair and Till, 2003). Two important sources of quenching are chemical quenching and color quenching. To correct for this a chemical or color quench curve needs to be established for each type of matrix to determine counting efficiency. A measure of counting efficiency is then used to convert CPM to disintegrations per minute (DPM) (Eq. 3), which can then be converted into Bq (1 Bq = 60 DPM) (FAO/IAEA, 2016).

$$\text{DPM} = \frac{\text{CPM}}{\text{Counting efficiency (as a decimal)}} \quad (3)$$

where DPM refers to disintegrations per minute and CPM refers to counts per minute.

The isotopic composition of the element is called the specific radioactivity, or the specific activity, which is the ratio of the radioactive isotope compared to the naturally occurring element (Nguyen et al., 2016). Specific activity is the ratio of radioactivity per unit of material (e.g., Bq of P-33 kg⁻¹ of soil) or per unit of the non-labeled element being traced (e.g., Bq of P-33 mg⁻¹ of P).

Radioactive isotopes can be obtained as 'carrier-free', i.e., with a negligible amount of the non-labeled element or with a 'carrier', i.e., with a substantial amount of non-labeled element. Since the number of radioactive atoms is extremely small, the problem with the latter is that the carrier may change the equilibrium of the system. However, the latter may be preferred in some cases for tracer studies.

Since radioactive isotopes decay over time, some approaches require that the measured activity be corrected back to the same reference or 'activation' date, i.e., activity at $t = 0$ (Blair and Till, 2003). This is particularly the case for radionuclides with short half-lives or when multiple measurements are carried out over a relatively long period of time (McLaren et al., 2017).

Radioactive isotopes to study soil pools and processes

Radioactive isotopes have been used as a tool to study nutrient pools and their transformation in soils for over 70 years (Frossard et al., 2011). They are an essential tool to directly assess the relative importance of abiotic and biotic pathways in soils. Here, several approaches are highlighted with some relevant examples to soil science applications. Since a large proportion of studies involving radioactive isotopes are carried out on phosphorus (P), here, P radionuclides (i.e., P-32 and P-33) are discussed as a model. However, many of the concepts can be applied to other radionuclides where applicable. A carrier-free radioactive isotope is the basis for most calculations mentioned below.

Isotopic dilution in soil-solution systems

The isotopic dilution principle involves the addition of a radioactive isotope to the soil system that will distribute uniformly between the soil solution and soil exchangeable pools (Hamon et al., 2008). The isotopic dilution principle is described in Eq. (4) (Hamon et al., 2002).

$$\frac{r_{\text{sol}}}{r_{\text{exch}}} = \frac{c_{\text{sol}}}{c_{\text{exch}}} \quad (4)$$

where r_{sol} refers to the activity of the radioactive isotope in the soil solution, r_{exch} refers to the activity of the radioactive isotope that is exchangeable, c_{sol} is the concentration of the element in the soil solution, and c_{exch} is the concentration of the element that is exchangeable.

Eq. (4) can be rearranged to calculate the concentration of the element that is exchangeable (Eq. 5).

$$c_{\text{exch}} = c_{\text{sol}} \times \frac{r_{\text{exch}}}{r_{\text{sol}}} \quad (5)$$

If a known quantity of a radioactive isotope is added to the soil system, it will distribute itself between the soil solution and soil exchangeable pools (Hamon et al., 2002). Consequently, the activity of the radioactive isotope that is exchangeable can be calculated as the difference between the activity of the radioactive isotope which was added to the soil system and that in the soil solution (Eq. 6).

$$r_{\text{exch}} = R_{\text{added}} - r_{\text{sol}} \quad (6)$$

where R_{added} refers to the activity of the radioactive isotope which was added to the soil system.

The concentration of the element that is exchangeable in soil can be determined when combining Eqs. (5) and (6) (Eq. 7) (Hamon et al., 2002). When converted to a soil weight basis (mg P kg^{-1}), the term 'E-value' is commonly used in the literature, which signifies "exchangeable". However, Hamon et al. (2002) suggests to use the term ' E_e ' to denote the concentration of the element that is exchangeable on the soil solid.

$$E_e = c_{\text{exch}} = c_{\text{sol}} \times \frac{(R_{\text{added}} - r_{\text{sol}})}{r_{\text{sol}}} \quad (7)$$

Eq. (7) can be rearranged so that the concentration of the element in the soil solution and exchangeable phase on the soil solid can be determined (Eq. 8). When converted to a soil weight basis (mg P kg^{-1}), this is considered the most bioavailable pool of the element in soil. Here, Hamon et al. (2002) suggests to use the term ' E_a ' to denote the concentration of the element in the soil solution and exchangeable phase on the soil solid.

$$E_a = (c_{\text{exch}} + c_{\text{sol}}) = c_{\text{sol}} \times \frac{R_{\text{added}}}{r_{\text{sol}}} \quad (8)$$

There are several assumptions that need to be met when applying the isotopic dilution principle in soil science contexts (Hamon et al., 2008; Frossard et al., 2011). These include: (1) the radioactive isotope that is added to the soil system should not alter the equilibrium conditions; (2) the radioactive isotope behaves in the same way as the stable isotope naturally present in the soil system; (3) the target element in the soil solution is isotopically exchangeable, and; (4) the added radioactive isotope is uniformly mixed with the non-labeled element being traced in the soil solution and exchangeable pool. While the isotopic dilution of a radioactive isotope within the soil system occurs in theory at infinite time, in practice an operationally defined time is routinely used (typically 1–3 days).

'Available' phosphorus in soil—Isotopically exchangeable phosphorus (E-value)

Numerous methods have been developed to estimate the pool of 'available' nutrients in soil. Historically, chemical extraction techniques have been the predominant method. The problem with this is that they are operationally defined and have the potential to cause artifacts, which often under- or over-estimate the pool of plant-available nutrients in soil. Measures of isotopically exchangeable P, or 'E-values', can provide an estimate of the 'available' or 'labile' pool of soil P based on the isotopic dilution principle (Frossard et al., 1994).

The determination of E-values typically involves the addition of a radioactive isotope to a soil suspension under equilibrium conditions. The soil to solution ratio, background solution, equilibration times, and periods of exchange time vary in the literature (Kuo, 1996; Di et al., 1997). However, a 1:10 or 1:20 soil to solution ratio, a background solution of H_2O or a dilute electrolyte (e.g., 0.01 M CaCl_2 , calcium chloride), and a 16 h equilibration time appears to be more common (Meyer et al., 2020). The activity of the radioactive isotope in the soil solution (i.e., r_{sol} in Eqs. 7 and 8) is highly dependent on the time of exchange. Therefore, this is typically designated as r_t and refers to the activity of the radioactive isotope in the soil solution after a period of isotopic exchange time t (Hamon et al., 2002).

The E-values are generally obtained on soil suspensions and are highly time dependent, therefore, Eqs. (7) and (8) need to be converted to a soil weight basis (mg P kg^{-1}) and reported at a given period of exchange time (Hamon et al., 2002). For example, Eq. (8) can be converted to take into account the dilution factor (i.e., the ratio of solution volume (L) to soil mass (kg)) and period of exchange time (Eq. 9) (Hamon et al., 2008).

$$E_t = D \times c_{\text{sol}} \times \left(\frac{R_{\text{added}}}{r_t} \right) \quad (9)$$

where D refers to the dilution factor of the soil suspension (i.e., volume of solution (L) divided by the soil mass (kg)), c_{sol} refers to the amount of the nutrient in the soil solution (mg L^{-1}), R_{added} refers to the total amount of activity of the radioactive isotope added to the soil suspension (Bq), and r_t refers to the activity of the radioactive isotope in the soil solution after a period of exchange time t (Bq).

It is not always clear if the reported E-values refer to an E_e or E_a value (Hamon et al., 2002). Although, the latter appears more prevalent and is primarily focused on pools of bioavailable P (Hamon et al., 2002). In general, differences between E_e and E_a values do not differ greatly (Hamon et al., 2008). In soils where r_t is small compared to R_{added} , then differences between E_e and E_a will be negligible. However, where r_t is large compared to R_{added} , then differences between E_e and E_a will be much greater. This is particularly the case in soils with a small P buffering capacity. Furthermore, differences between E_e and E_a will be greater with decreasing periods of exchange time as r_{sol} decreases with time.

Caution is needed when carrying out measures of isotopic exchange in soils with very small concentrations of soil solution P and large P sorption capacity (Kuo, 1996). This is because the concentration of P in the soil solution is often $<10 \mu\text{g P L}^{-1}$, which is difficult to measure accurately by colorimetric approaches (Randriamanantsoa et al., 2013). Nevertheless, various approaches have been developed to measure concentrations as small as $0.8 \mu\text{g P L}^{-1}$ (Randriamanantsoa et al., 2013).

Several studies report E-values in soils under a diverse array of applications (Di et al., 1997; Nguyen et al., 2016). For example, Meyer et al. (2020) determined pools of isotopically exchangeable P within 24 h ($E_{24\text{h}}$) on a range of soils to assess the pool of potentially plant-available P. The authors treated soils with different types and amounts of fertilizer in an incubation experiment. They found differences in $E_{24\text{h}}$ -values among soil types and also that among fertilizer combinations. Most notably, the addition of potassium (K) with P as monoammonium phosphate in a concentrated zone resulted in a decrease in $E_{24\text{h}}$ -values in some soil types compared to that in the absence of K.

Soil phosphorus dynamics—Phosphorus isotope exchange kinetics (IEK)

For over 70 years, the activity of the radioactive isotope (P-32 and P-33) in soil solution was known to decrease with time (Frossard et al., 2011). McAuliffe et al. (1948) investigated the reaction of P-32 in a soil-water suspension under equilibrium conditions. The authors describe two main types of phosphate reaction between the soil solution and soil surface with time. The first was interpreted as a pool of readily exchangeable P and the second as a pool of less exchangeable P. This was later described using a simple power function (Morel et al., 1989) (Eq. 10).

$$\frac{r(t)}{R_{\text{added}}} = \left[\frac{r(1)}{R_{\text{added}}} \right] t^{-n} \quad (10)$$

where t refers to the period of isotopic exchange in minutes, $\frac{r(1)}{R_{\text{added}}}$ is the proportion of activity in the soil solution after 1 min of isotopic exchange relative to that of the total activity added to the soil system, and n is a model parameter that describes the rate of removal of activity in solution.

The simple power equation describing the reaction of P-32 in the soil solution with the soil surface was found to be inadequate because of the long periods of time needed to reach a final isotopic equilibrium. Fardeau (1995) proposed that the exchange of radioactive phosphate could be characterized by its kinetic parameters obtained in an isotopic exchange kinetics (IEK) experiment. Briefly, this involves a soil suspension (10 g of soil in 99 mL of H_2O) under equilibrium conditions. At time $t = 0$, a 1 mL aliquot of a radioactive isotope (P-32 or P-33) solution is added, and the soil suspension sampled with a syringe and filter at increasing periods of isotopic exchange time (e.g., 1 min, 4 min, 10 min, 30 min, 60 min, and 90 min). Consequently, Fardeau et al. (1985) adapted the power function so that a final isotopic equilibrium was no longer necessary (Eq. 11). See Fig. 1 for an example of a P IEK experiment on a soil.

$$\frac{r(t)}{R_{\text{added}}} = m \left(t + m^{\frac{1}{n}} \right)^{-n} + \frac{r_{\infty}}{R_{\text{added}}} \quad (11)$$

where m and n are model parameters derived from the nonlinear regression, r_{∞} refers to the activity of the radioactive isotope in the soil solution at final isotopic equilibrium, $\frac{r_{\infty}}{R_{\text{added}}}$ is the proportion of activity of the radioactive isotope in the soil solution at the final isotopic equilibrium to that of the total activity added to the soil system.

The term $\frac{r_{\infty}}{R_{\text{added}}}$ describes the ratio of r_{sol} to R_{added} at the final isotopic equilibrium or the maximum dilution of the added radioactive isotope by inorganic P in the soil system (Di et al., 1997). It has been operationally defined as the ratio of P in the soil solution or c_{sol} (mg P kg^{-1}) and the pool of soil inorganic P (mg P kg^{-1}) (Eq. 12) (Frossard et al., 2011). The parameter m indicates the immediate physicochemical reactions that occur in soils, and corresponds to the proportion of activity in the soil solution compared to that of the total activity added after a period of isotopic exchange of 1 min (or $\frac{r(1)}{R_{\text{added}}}$) (Achat et al., 2016). The parameter n indicates the slow physicochemical reactions, and accounts for the rate of removal of radioactive P from the soil solution with isotopic exchange times longer than 1 min. In general, phosphate reactivity with the soil solid phase will increase when values of n increase or values of m decrease. Furthermore, the buffering capacity of P of the soil increases with decreasing values of m or increasing values of n .

Fig. 1 An example of a P isotopic exchange kinetics experiment (IEK) using P-32 (and P-33) on a Ferralsol soil collected from the Highlands of Madagascar, as reported in [Randriamanantsoa et al. \(2013\)](#). The proportion of activity of P-32 (and P-33) in the soil solution (r) to that of the total activity added (R) decreased with increasing time of exchange (1 min, 4 min, 10 min, 40 min, 60 min, and 80 min). A nonlinear model was fitted to the data (see Eq. 11). Furthermore, the authors found that there was no systematic isotopic fractionation between P-32 and P-33 during the experiment, suggesting these radionuclides have a similar behavior when undergoing isotopic exchange. Reprinted from Randriamanantsoa L, Morel C, Rabeharisoa L, Douzet J, Jansa J, Frossard E (2013) Can the isotopic exchange kinetic method be used in soils with a very low water extractable phosphate content and a high sorbing capacity for phosphate ions? *Geoderma* **200–201**: 120–129, Copyright (2013), with permission from Elsevier.

$$\frac{r_{(\infty)}}{R_{\text{added}}} = \frac{D \times c_{\text{sol}}}{P_{\text{inorg}}} \quad (12)$$

where P_{inorg} refers to the concentration of inorganic P in soil.

The P IEK approach involves homo-ionic exchange of the added radioactive isotope (P-32 or P-33) in the soil solution with the pool of desorbable P on the soil solid phase ([Frossard et al., 2011](#)). It provides information on the factors quantity (Q), intensity (I), and capacity (C) of available P in soil ([Nguyen et al., 2016](#)). The factor Q is the amount of ‘available’ P in soil and is obtained from the calculation of E-values (Eq. 9), the factor I is the concentration of P in the soil solution and is measured directly (i.e., c_{sol}), and factor C is the ability of the soil to resist changes in soil solution P and is obtained from the rate at which the radioactive isotope is removed from the soil solution.

The P IEK approach reveals that inorganic P in soil should be considered a continuum of P from immediately available to slowly available, rather than a distinct number of pools designated as available or non-available ([Nguyen et al., 2016](#)). The model proposed by [Fardeau et al. \(1985\)](#) based on a short-term kinetic (up to 100 min) can derive long-term kinetics (3 months or more). A pluricompartimental model was proposed to describe the quantity of exchangeable P based on plant P uptake ([Fardeau, 1995](#)). This included: (1) the pool of exchangeable P within 1 min, which comprises P in the soil solution and that immediately transferable to the soil solution; (2) the pool of exchangeable P within 1 min and 24 h, which is based on the average time of active plant P uptake by a root part; (3) the pool of exchangeable P within 1 day and 3 months, which is based on the average time of active plant P uptake by a root system, and; (4) the pool of exchangeable P that is greater than 3 months.

The model also enables the calculation of several measures of P dynamics ([Fardeau, 1995](#)). This includes: (1) the average turnover (or exchange) rate between inorganic P on the soil solid phase and in the soil solution (K_m in min^{-1} , also referred to as g_m) (Eq. 13); (2) the average residence time of inorganic P in the soil solution (T_m in min) (Eq. 14), and; (3) the average flux of exchange between inorganic P on the soil solid phase and in the soil solution (F_m in $\text{mg P kg}^{-1} \text{ soil min}^{-1}$) (Eq. 15).

$$K_m = \frac{n}{m^{(1/n)}} \quad (13)$$

where K_m refers to the average turnover (or exchange) rate between inorganic P on the soil solid phase and in the soil solution, and the parameters m and n are obtained from the model.

$$T_m = \frac{1}{K_m} \quad (14)$$

where T_m refers to the average residence time of inorganic P in the soil solution.

$$F_m = D \times c_{\text{sol}} \times K_m \quad (15)$$

where F_m refers to the average flux of exchange between inorganic P on the soil solid phase and in the soil solution.

The P IEK approach provides important information on the amount and transfer of P in soil systems, which are related to various soil properties (Achat et al., 2016) and plant P uptake (Fardeau, 1995). Furthermore, the P IEK approach has provided detailed information on the P status and dynamics of a diverse range of soils, which could predict crop responses, and the likelihood of crop responses to P fertilization (Frossard et al., 2000).

Gross phosphorus mineralization

The turnover of soil organic matter is an important source and sink of available P in soil (Frossard et al., 2000). Quantifying the amount of mineralizable organic P in soil can be difficult (Di et al., 1997), but estimates are possible based on the isotopic dilution principle (Bünemann, 2015). Essentially, the pool of isotopically exchangeable P in soil is labeled with a radioactive isotope (P-32 or P-33). The P in soil organic matter will not be labeled with the radioactive isotope, therefore, any mineralization of organic P will increase the concentration of P in the pool of isotopically exchangeable P and dilute the radioactive isotope (P-32 or P-33). Pools of exchangeable P (E-values) will be greater in the biologically active soil where abiotic and biotic processes occur, relative to that in a sterile soil where only abiotic (physicochemical reactions) processes occur. The difference in E-values between the two soils is considered the amount of inorganic P in soil that has come from the mineralization of organic P within a given period of time (Frossard et al., 2011).

The isotopically exchangeable pool of P (E-values) due to physicochemical processes is typically obtained by a P IEK experiment on the preincubated and unlabeled soil, which is extrapolated and forms the baseline of physicochemical processes (Bünemann, 2015). The isotopically exchangeable pool of P (E-values) due to physicochemical and biological or biochemical processes is typically obtained using a soil incubation experiment that has been labeled with a radioactive isotope (P-32 or P-33) (Oehl et al., 2004). After a given period of time, water extractions are carried out and the specific activity determined to calculate E-values (Bünemann, 2015). The outcome is the difference in relative specific activity and E-values between the baseline and biologically active soil (Fig. 1). Phosphorus immobilization can also be estimated by measuring the soil microbial biomass in the incubation experiment (Bünemann, 2015) (Fig. 2).

The above approach of estimating gross mineralization of organic P in soil has been simplified and there are many other factors to consider (Bünemann, 2015). Nevertheless, it is important that the experiment be carried out at steady-state equilibrium, a low and constant rate of respiration, a constant concentration of soil solution P, and a relatively short incubation period (7–14 days) to minimize any remineralization of organic P that had been labeled subsequently (Frossard et al., 2011; Nguyen et al., 2016).

Studies reporting the gross mineralization of organic P in soil based on the isotopic dilution principle are limited (Bünemann, 2015). Oehl et al. (2004) investigated the rates of mineralization of organic P in an incubation experiment with soils from a long-term field experiment in Switzerland. The authors reported that the rates of basal mineralization of soil organic P ranged from 1.4 to 2.5 mg P kg⁻¹ d⁻¹, which was less than the pool of isotopically exchangeable P due to physicochemical processes. This highlights the importance of physicochemical processes in supplying plant-available P at this site. Furthermore, rates of mineralization of soil organic P were larger for the biodynamic treatment than for the mineral fertilizer treatment.

Fig. 2 The isotopic dilution principle used to estimate the gross mineralization rates of organic P in soil, as reported in Bünemann (2015). (a) The relative specific activity (r_t/R) in soil water filtrates that have been obtained using P IEK experiments and extrapolated (physicochemical processes), and also from a soil incubation experiment labeled with P-32 or P-33 (plus biological or biochemical processes). (b) Measures of E-values were obtained as the inverse of the relative specific activity. Isotopic dilution in soil-plant systems

'Available' phosphorus in soil—isotopically exchangeable phosphorus (L-value)

Measures of isotopically exchangeable P can also be obtained from soil-plant systems based on the isotopic dilution principle. The term 'L-value' refers to "Larsen" values of soil P that are associated with pools of labile P in the soil (Frossard et al., 2011). It estimates the quantity of isotopically exchangeable P in soil based on the specific activity of P in the plant (Larsen, 1967).

The determination of L-values typically involves the addition of a radioactive isotope to a soil system, which is thoroughly mixed and allowed to reach equilibrium between the added radioactive isotope and the pool of exchangeable P in soil (Nguyen et al., 2016). Nevertheless, equilibrium may not be obtained in practice particularly in soils with recent additions of fertilizer P (Di et al., 1997). Plants are then grown in the radiolabeled soil and the specific activity of shoots measured (Frossard et al., 2011). The L-value can be calculated using Eq. (16).

$$L = (c_{\text{shoot}} - c_{\text{seed}}) / \left(\frac{r_{\text{shoot}}}{R_{\text{added}}} \right) \quad (16)$$

where c_{shoot} refers to the amount of total P in the shoot, c_{seed} is the amount of P from the seed that is contributing to the total P in the shoot, and r_{shoot} refers to the activity of the radioactive isotopes in the shoot.

The L- and E-values should be similar based on a conceptual basis, but they can differ based on several factors (Di et al., 1997). This is partly because measuring L-values involve plants, which have various P acquisition strategies to mobilize soil P. In contrast, measuring E-values involves a soil suspension in the absence of a plant. There are many soil-based processes that occur in the rhizosphere, which may change the specific activity. The measurement of L-values is generally carried out experimentally over a much longer time period than that of E-values. Last, the contribution of seed P to that of shoot P can be difficult to quantify, particularly at early growth stages (Frossard et al., 2011).

Many studies have shown positive relationships between E- and L-values for the majority of crops at similar periods of exchange time (Frossard et al., 2011). For example, Frossard et al. (1994) compared E-values within a 13 week period and that of L-values in common bentgrass (*Agrostis capillaris* L.) across 10 diverse surface soils grown in pots. The authors found that E- and L-values were strongly correlated (see Fig. 3), which highlights the importance of the isotopically exchangeable pool of P for plant P uptake.

Radioactive isotopes to study the fate of fertilizer

There are several approaches to assess the fertilizer-use efficiency of P by crops, and each has its advantages and disadvantages (Johnston et al., 2014). Radioactive isotopes have been an important approach for tracking the fate of fertilizer P in soil-plant systems for over 70 years (Frossard et al., 2011). Furthermore, radioactive isotopes can also be used to assess the fate of fertilizer P into different soil fractions and the extent of their movement over time (McLaren et al., 2017).

Fig. 3 Measures of L-values obtained on common bentgrass (*Agrostis capillaris* L.) across ten diverse soils, including those that had received phosphate fertilizer after 13 weeks of growth, and that of E-values obtained on the soils based on P isotopic exchange kinetics and extrapolated to 13 weeks of exchange, as reported in Frossard et al. (1994). There was a strong correlation between the reported L- and E-values. Reprinted from the Soil Science Society of America Journal, 58, Frossard E, Morel JL, Fardeau JC, Brossard M, Soil Isotopically Exchangeable Phosphorus: A Comparison between E and L Values, 846–851, Copyright (1994), with permission from John Wiley and Sons.

Direct labeling approach

The direct labeling approach involves labeling the source with a radioactive isotope and provides direct information on the fate of fertilizer P in soil-plant systems (McLaughlin et al., 2011). The approach has been widely used in a variety of agricultural contexts and is based on the homogenous labeling of a fertilizer source (solution or powder) with a radioactive isotope (Frossard et al., 2011). This can involve dissolving a fertilizer (e.g., monocalcium phosphate) and then adding the radioactive isotope (P-32 or P-33) to the solution, which can then be added to the soil in liquid form. Alternatively, the labeled fertilizer can be precipitated out and a dry powder is formed, or radiolabeled granules can be made (McLaren et al., 2017). In addition, radiolabeled plant residues can be made by growing plants in a soil or solution containing the radioactive isotope (P-32 or P-33), and the shoots subsequently harvested and dried for later experiments and analyzes (McLaughlin et al., 1988).

The specific activity of the sample analyzed (e.g., plant shoots or a soil extract) and that of the added fertilizer (e.g., MBq of P-33 mg^{-1} of P) is then used to calculate the amount of P in the sample derived from the fertilizer (Eq. 17) (Frossard et al., 2011). See Fig. 4 for an example of the percentage of plant P derived from the labeled fertilizer ($Pdff$ (%)).

$$Pdff (\%) = 100 \left(\frac{SA_{+P}}{SA_f} \right) \quad (17)$$

where $Pdff$ (%) is the percentage P in the plant derived from the labeled fertilizer, SA_{+P} refers to the specific activity of P in the plant from fertilized treatments, and SA_f refers to the specific activity of the labeled fertilizer.

The ability to label the source with a radioactive isotope is a powerful technique to assess its fate in the soil-plant system. The fate of a variety of fertilizer sources, organic compounds, and plant residues can be assessed. However, there are several limitations to the direct labeling approach. These can include: (1) difficulty to label the material homogeneously; (2) radioactive isotopes with short half-lives favor laboratory- and glasshouse-based experiments rather than field-based experiments, and; (3) tracking the fate of fertilizer P over several growing seasons or assessing the contribution of P in plants from residual pools is either difficult or not possible.

Many studies have investigated the fate of fertilizer P in soil-plant systems using the direct labeling approach, and several have been carried out under glasshouse conditions over relatively short periods of time. Nevertheless, some studies have applied the direct approach under field conditions (McLaughlin et al., 1988). For example, McLaren et al. (2017) investigated the fate of P-33 labeled single superphosphate granules in subterranean clover (*T. subterraneum* L.) pastures grown under field conditions. The authors found that about 50% of the added fertilizer P was recovered in clover shoots, whereas about 20–25% of the added fertilizer P was recovered in the 0–4 cm soil layer and predominantly as inorganic P (Fig. 5). A further 5–15% of the added fertilizer P remained in the granule at the end of the growing season. The authors also reported that early-season applications of fertilizer P to the soil surface was generally the best strategy to improve pasture recovery of fertilizer P.

Indirect labeling approach

There are many contexts where it is not possible to label the source homogeneously (Frossard et al., 2011). These can include animal manures, composts, natural minerals (e.g., rock phosphate), and waste materials. The indirect labeling approach provides an

Fig. 4 The percentage of P in subterranean clover (*Trifolium subterraneum* L.) shoots derived from the labeled fertilizer ($Pdff$ (%)) across three concentrations of initial soil P fertility (P0: 4–6 mg Olsen–P kg^{-1} , P1: 10–15 mg Olsen–P kg^{-1} , and P2: 20–25 mg Olsen–P kg^{-1}) on an acidic Luvisol located near Hall, Australia, as reported in McLaren et al. (2017). The direct labeling approach was used in the study. The authors found that the percentage of shoot P derived from the labeled fertilizer was highest in the P0 treatment compared to that in the P1 and P2 treatments, and decreased with time. Reprinted from McLaren TI, McBeath TM, Simpson RJ, Richardson AE, Stefanski A, Guppy CN, Smernik RJ, Rivers C, Johnston C, McLaughlin MJ (2017) Direct recovery of ^{33}P -labelled fertiliser phosphorus in subterranean clover (*Trifolium subterraneum*) pastures under field conditions – The role of agronomic management. *Agriculture, Ecosystems & Environment* **246**: 144–156, Copyright (2017), with permission from Elsevier.

Fig. 5 Recovery of fertilizer P in various components of a subterranean clover (*Trifolium subterraneum* L.) pasture at two sites in the high rainfall zone of south-eastern Australia based on the direct labeling approach (P-33 labeled single superphosphate), as reported in McLaren et al. (2017). Reprinted from McLaren TI, McBeath TM, Simpson RJ, Richardson AE, Stefanski A, Guppy CN, Smernik RJ, Rivers C, Johnston C, McLaughlin MJ (2017) Direct recovery of ^{33}P -labelled fertiliser phosphorus in subterranean clover (*Trifolium subterraneum*) pastures under field conditions – The role of agronomic management. *Agriculture, Ecosystems & Environment* **246**: 144–156, Copyright (2017), with permission from Elsevier.

opportunity for the fate of a complex source to be tracked in the system. This involves labeling the isotopically exchangeable pool of soil P with a radioactive isotope, including the fertilized and non-fertilized treatments. The specific activity of samples (e.g., plant shoots or a soil extract) in the fertilized and non-fertilized treatments is determined, which can then be used to calculate the amount of P in the sample derived from the fertilizer (Eq. 18) (Frossard et al., 2011).

$$Pdff (\%) = 100 \left(1 - \frac{SA_{+P}}{SA_{-P}} \right) \quad (18)$$

where SA_{+P} refers to the specific activity of P in the plant from the fertilized P treatments, and SA_{-P} refers to the specific activity in the plant from the non-fertilized P treatments.

An important assumption of the indirect approach is that the specific activity of the isotopically exchangeable pool of P is similar in the fertilized and non-fertilized soils (Frossard et al., 2011). Any release of inorganic P from the added non-labeled fertilizer will dilute the radioactive isotope (P-32 or P-33). However, a possible issue with this approach is that the addition or presence of some organic material can also affect the specific activity by causing immobilization of P or by stimulating P mineralization of the native organic P present in the soil, which was not labeled. The consequence is that the specific activity of the soil solution of the fertilized treatment will be affected and provide unreliable results on the percentage of plant P derived from the organic fertilizer (called 'pool substitution') (Frossard et al., 2011).

Limitations of radiotracers

Radioactive isotopes (P-32 and P-33) are an important tool to probe nutrient pools and their transformation in soil, and as tracers to assess the fate of fertilizers in soil-plant systems. However, there are several limitations that need to be considered. The first is that radioactive isotopes emit ionizing radiation, which makes their use more restrictive due to various safety and government regulations. The second is that each radioactive isotope has a half-life, which tends to favor short-term and laboratory-based experiments compared to that of long-term and field-based experiments. In general, long half-lives are more favorable particularly for glasshouse or field experiments. However, long half-lives can also be problematic due to issues with their safe disposal. Another issue associated with this is that the activity of radioactive isotopes is decreasing which requires that they are used and analyzed in a timely manner. Consequently, if there is surplus activity to requirements, radioactive isotopes with short half-lives cannot be stored and used at a later date.

Future opportunities for radiotracers

There are several radioactive (and stable) isotopes available to study soil pools and processes. Many studies have been carried out using a single isotope. However, it will be important to combine multiple isotopes and analytical approaches to obtain a holistic

view of nutrient cycling. For example, combining C-14, N-15, and P-33 isotopes to better understand soil organic matter turnover. Furthermore, future research tracking the fate of fertilizers into specific nutrient pools will provide improved insight into the processes that are important in their accumulation or depletion in soil. For example, assessing the relative contribution of fertilizer P into specific forms of organic P (e.g., *myo*-inositol hexakisphosphate) might help develop strategies to reduce their stabilization and improve crop and pasture recovery of the added fertilizer P. In contrast, where the accumulation of soil organic matter is limited by P, radioactive isotopes may help to identify how the P component of organic matter in soil accumulates.

Conclusions

The use of radioactive isotopes has greatly improved our understanding of soil pools and process. The isotopic dilution principle is an important approach when applying radioactive isotopes in soil science contexts. Pools of isotopically exchangeable P are highly relevant for plant availability, and the dynamics of P between the soil solution and soil solid phases are important at assessing P availability and transfer. Furthermore, tracer approaches provide direct information on the fate of fertilizer P in soil-plant systems, and can provide quantitative measures of the crop recovery of fertilizer P and how this is affected by differing agronomic management strategies. Radioactive isotopes will continue to be an important tool to help understand nutrient cycles, which will also help to address major challenges of global concern (e.g., food security and climate change).

Abstract

Metal isotopes can be used to improve the understanding of the dynamics of chemical elements in the soil–plant–water–atmosphere system. Some bio-physicochemical processes induce metal isotope fractionation, which is measurable by mass spectrometry. Therefore, isotope analysis of metals can contribute to the understanding of pedogenetic processes, metal source, i.e. natural or anthropogenic, as well as the processes affecting them if they induce isotope fractionation.

Key points

- Metal isotopes can improve understanding of the dynamics of chemical elements in the soil–plant–water–atmosphere system
- Metal isotopes can contribute to the understanding of pedogenetic processes
- Metal source can be determined by isotope analysis
- Fractionation processes may help to understand weathering processes in soil

Introduction

The Critical Zone extends from the top of the lithosphere to the base of the atmosphere. It is our living environment and supports human activities. The Critical Zone and in particular the ‘soil’ compartment are places of exchanges, interactions and transformation of matter and energy, that further control water and soil quality (Chorover et al., 2007). Many bio-physicochemical interactions that control the biogeochemical cycles of elements, including metals and metalloids, occur in soil. These metals, of which some are essential nutrients, can have a natural or anthropogenic origin. Furthermore, bio-physicochemical processes (e.g. redox changes, sorption, complexation, biological uptake) can affect metal aqueous or solid speciation.

Isotopes, stable or radioactive, can be used to improve understanding of the dynamics of chemical elements in the soil–plant–water–atmosphere system. Isotopes of an element have the same number of protons in their nucleus, but have a different number of neutrons, which gives them different masses. Stable isotope analysis of the ‘light’ elements (or traditional stable isotopes) C (carbon), N (nitrogen), O (oxygen), S (sulfur), and H (hydrogen) has been used for several decades to understand their cycle in the environment and in plants. Some bio-physicochemical processes induce isotopic discrimination and, although weak, this discrimination (or fractionation) is measurable by mass spectrometry. The isotope analysis of metals can also contribute to an understanding of their source, i.e. natural or anthropogenic, as well as the processes affecting them if they induce isotope fractionation. Recent developments in mass spectrometry, in particular the improvement of multi-collector inductively-coupled-plasma mass-spectrometers (MC-ICP-MS) and their installation in many laboratories, now make possible to analyze the stable isotopes of almost the whole periodic table with enough analytical precision (Wiederhold, 2015; Komárek et al., 2021). New perspectives are thus opened to understand the biogeochemical cycles of metals in soils and more broadly in the environment.

Non-traditional isotope geochemistry

Formalism in isotope geochemistry

For elements having more than one isotope, bio-physicochemical processes can result in isotope fractionation, i.e. a subtle modification of isotope abundances between the reactant and the product of the reaction. In this case, enrichment in one isotope in a reservoir will be compensated by its equivalent depletion in the other reservoir, and the isotope balance of the global system remains unchanged. This chapter describes how isotope fractionation can occur during mineral dissolution or precipitation, during mineral adsorption or organic complexation if the reaction is incomplete or follows a unidirectional pathway (see details in [Wiederhold, 2015](#)). The development of non-traditional isotope systems for 20 years (in contrast with C, H, O, N and S isotopes) has been mostly due to the advent of MC-ICP-MS, enabling fast and accurate measurements for numerous isotope systems. High-precision isotope values were also obtained through the strengthened development of efficient and size-reduced chromatographic separations with anionic or cationic exchange resins (e.g. [Conway et al., 2013](#) for Fe (iron), Cu (copper) and Zn (zinc) isotopes). A minimization of procedural blanks, isobaric interferences and/or matrix effects enable scientists to determine isotope ratios at nano- or sub-nanogram scale ([Albarède and Beard, 2004](#)). In addition, methods of post-analysis correction (e.g. double-spike or doping techniques) markedly increased measurement precision and reproducibility, allowing identification of small but resolvable isotope variability and fractionation.

With the ability of mass spectrometry to measure isotope ratios accurately rather than isotope abundances, isotope signatures are reported following a delta notation:

$$\delta^i X = \left[\frac{(^iX)_{\text{sample}}}{(^iX)_{\text{standard}}} - 1 \right] 1000 \quad (1)$$

where i and j are the heavier and the lighter isotopes of the element X , respectively. It must be borne in mind that variation of the isotopic signature relative to the standard, when it exists, is very low, and the reason why the delta value is expressed in ‰.

The isotope fractionation $\alpha_{A/B}$ between two compounds A and B is defined as the ratio of their respective isotope ratio R_A and R_B :

$$\alpha_{A/B} = \frac{^{i/j}R_A}{^{i/j}R_B} = \frac{\delta^i X_A + 1000}{\delta^i X_B + 1000} \quad (2)$$

Since $\alpha_{A/B}$ is close to unity, a convenient approximation can be inferred:

$$\Delta_{A-B} = \delta^i X_A - \delta^i X_B \approx 1000 \ln \alpha_{A/B} \quad (3)$$

Equilibrium vs kinetic isotope fractionation

Stable isotope fractionation in natural samples can be of either a kinetic or equilibrium nature. The only exceptions are mass-independent fractionation and nuclear volume effects that will affect odd and even isotopes differently for some elements (mostly iron and mercury (Hg), ([Wiederhold, 2015](#)) in specific contexts and that are not within the scope of this study.

Kinetic isotope fractionation occurs when isotopes of an element are affected by different rates of reaction, typically because of their mass differences. In other words, lighter isotopes react faster than heavier ones, resulting in a light isotope enrichment in the reaction product. This regime is typically seen for diffusion or evaporation/condensation processes, biological reactions that are enzymatically mediated or during the initiation time of adsorption, precipitation, or complexation reactions. The evolution of a system where kinetic isotope effects are dominant is classically modelled using a Rayleigh fractionation law, describing the instantaneous isotope signature of products which are physically (e.g., evaporation) or chemically (e.g., mineral precipitation) isolated from reactants.

Equilibrium isotope fractionation occurs when forward and backward transformations proceed at similar rates. In this system, enrichment in heavy or light isotopes in the product will be related to the free energy of isotope exchange reactions, which depends on the strength of the molecular bonds ([Bigeleisen and Mayer, 1947](#)). In other words, phases or products which form stiffer bonds will be enriched in heavy isotopes ([Schauble et al., 2009](#)). In the case of adsorption or complexation reactions, a larger bond stiffness is directly related to a lower coordination number and/or to shorter bond lengths between the element of interest and its neighbors. For abiotic or biotically-mediated redox processes, the oxidized species is generally enriched in heavy isotopes. The advantage of equilibrium fractionation is that it can be easily determined through experimental studies in the laboratory (details in [Komárek et al., 2021](#)) or calculated using numerical ab initio models (see [Fujii et al., 2014](#) in [Moynier et al., 2017](#)). In comparison, the magnitude of kinetic isotope fractionation is often difficult to approximate due to the progressive shift observed for most reactions from a kinetically-driven to an equilibrium-driven regime, which is particularly true for metals and metalloids. However, recent studies performed on soils, and more generally in the critical zone report that recorded silicon, Si (and presumably iron) isotope signatures conserve a mixture of both kinetic and equilibrium fractionation; the isotope expression of these two regimes of fractionation depending on the rates of formation of the mineral (see [Oelze et al., 2015](#) in [Poirasson, 2017](#)).

Isotopes and pedogenetic processes

Weathering and formation of secondary clay minerals

In soils, weathering processes control the formation of secondary minerals, such as clay, oxide, or hydroxide minerals. These major pedogenetic processes release the most soluble elements in soil solution such as alkalis (Na (sodium), K (potassium)), alkaline-earths (Ca (calcium), Mg (magnesium)) or silicon for the major ones and affect the elemental dynamics in both soil and soil solution. Clay minerals, i.e. phyllosilicates, precipitated from the weathering of silicate primary minerals, result in the association of an SiO_4 tetrahedral sheet with octahedral layers of either Al (aluminum), Fe or Mg. They are responsible for many of the soil's most important physical and chemical properties, such as cation exchange and shrink-swell properties. To date, Li (lithium), Si and Mg isotope systems (reported as $\delta^7\text{Li}$, $\delta^{30}\text{Si}$ and $\delta^{26}\text{Mg}$, respectively), are the most efficient to track the weathering conditions leading to the formation of clay minerals since they all fractionate during clay formation.

Despite being a trace metal, Li presents three main advantages for use as a tracer of the weathering process in soils (details in Penniston-Dorland et al., 2017). First, with its low atomic mass, considerable isotope fractionation is observed during water-rock interactions (from 38 to 45‰). Second, Li is not involved in plant chemistry or primary productivity cycling, and third, its small content in carbonates compared with silicates, means that variations in the Li isotope are primarily controlled by silicate weathering. During clay formation in soils, light Li isotopes are preferentially incorporated, leaving a soil solution enriched in heavy isotopes (Penniston-Dorland et al., 2017). The extent of the isotope fractionation is mineral-dependent (amorphous allophane fractionates more Li isotopes than clay minerals) and is thus associated with the weathering regime. Interestingly, recent work in Puerto Rico, where the highest rates of silicate weathering have been documented, demonstrates that Li isotopes provide evidence of the decoupling that exists between the soil solution and stream waters drained out of the system. The former traces the secondary mineral dissolution occurring in the higher part of the profile while stream water coincides with the transformation of bedrock to secondary minerals at the bedrock-saprolite interface (Chapela Lara et al., 2022). However, as a trace and soluble element, Li isotope application can be difficult in soils developed under extreme weathering conditions (e.g. tropical soils) or on volcanic islands where high Li depletion is observed and because eolian additions (either from marine aerosols or dust) represent a dominant Li input, making the understanding of Li cycling more complex at the scale of a weathering profile.

In comparison with Li, Si, the main constituent of clays with oxygen, can be more suitable. Its higher mass and one single valence explain the smaller range of terrestrial Si isotopic variation observed in soils (Fig. 1). As for Li, light Si isotopes are preferentially incorporated into secondary clay minerals and also during adsorption onto iron or aluminum oxides while the soil solution and stream waters carry heavier $\delta^{30}\text{Si}$ (details in Poitrasson, 2017). In bulk soils, $\delta^{30}\text{Si}$ decreases linearly with increasing degree of weathering, expressed as the chemical index of alteration (CIA) in Fig. 1:

$$\text{CIA} = (\text{Al}_2\text{O}_3) / (\text{Al}_2\text{O}_3 + \text{CaO} + \text{Na}_2\text{O} + \text{K}_2\text{O}) * 100$$

The CIA, which shows the importance of the leaching of base cations (Ca^{2+} , Na^+ , K^+) during weathering, is compatible with the formation of cation-depleted clay (e.g., kaolinite) with lower $\delta^{30}\text{Si}$ rather than swelling clay (e.g., smectite) at higher CIA, i.e., when

Fig. 1 Evolution of composition of the soil Si isotope singature with the Chemical Index of Alteration (CIA). The figure is adapted with recent data from the original diagram of Opfergelt S and Delmelle P (2012) Silicon isotopes and continental weathering processes: Assessing controls on Si transfer to the ocean. *Comptes Rendus Geoscience* 344: 723–738.

Al content relative to Si is higher (Opfergelt and Delmelle, 2012). The general trend between $\delta^{30}\text{Si}$ and CIA in bulk soils from various regions and contexts shows that weathering intensity rather than climate or lithology seems to influence recorded $\delta^{30}\text{Si}$ in soils. This concept is supported by the variation in $\delta^{30}\text{Si}$ reported in soils for a single clay mineral, but which was precipitated under different weathering conditions (e.g., Cornelis et al., 2019; Guinoiseau et al., 2021). The advantage of the Si isotope system is because during chemical weathering, both kinetic and equilibrium fractionation (see above) can be preserved in clay minerals. The isotope expression of these two fractionation regimes depends on the rate of clay formation. Significant isotope fractionation toward lighter isotope values in minerals is typical of a kinetically driven mechanism and characteristic of high rates of formation during intense weathering activity. Equilibrium-driven fractionation is almost negligible and characteristic of low rates of formation and moderate weathering intensity in soils (details in Guinoiseau et al., 2021). This finding is consistent with experimental and theoretical calculations of isotope fractionation showing that most of fractionation in soils is of kinetic origin (Poitrasson, 2017). The main advantage is that the rates of mineral formation can in turn be linked to environmental conditions, such as fluid residence time at the time of mineral precipitation. For example, Guinoiseau et al. (2021) have shown that the Si isotopes along a lateritic profile depend on the rapidity with which rainwater is percolating downwards through soil porosity, and that in such a context they can reveal the past evolution of climate in the tropics. Under highly weathered environments (right part of the Fig. 1), Si isotopes can also efficiently trace cycles of dissolution–reprecipitation of silicate material (clays but also silcrete, i.e. silicon duricrust) when the weatherable mineral reserve becomes exhausted and that newformed clays start to dissolve (Opfergelt and Delmelle, 2012).

The idealized view of the Si isotope system should be slightly nuanced because Si, as a nutrient, will have its isotope signature in superficial soil horizons impacted by biological cycling, namely through silicon uptake by plants and or the production of phytoliths. Even if the weathering process can be catalyzed by biological activity, the latter may appear as a complicating factor when trying to use Si isotopes to identify silicate weathering, especially in a soil where Si cycling is dominated by biological overprinting (e.g. Riotte et al., 2018).

Finally, Mg is by far the most complex isotope system due to the variability in $\delta^{26}\text{Mg}$ between primary minerals of igneous and sedimentary rocks, to its involvement in carbonate rocks and the effect of biological cycling on its fate in soils (details in Guo et al., 2019). A large variability of $\delta^{26}\text{Mg}$ (from -1.64 to $+0.65\text{‰}$) is observed in soil profiles because of the preferential incorporation of light isotopes in carbonates, the variable $\delta^{26}\text{Mg}$ fractionation associated with Mg transport between biological compartments (root, stem, leaves) during plant growth, or the versatility of $\delta^{26}\text{Mg}$ recorded in clays (details in Teng, 2017). Magnesium can be incorporated in the octahedral sheet of clay minerals with a preference for heavy Mg isotopes (see Wimpenny et al., 2014 in Teng, 2017). A second Mg pool, commonly considered as exchangeable Mg, occurs as adsorbed Mg through electrostatic interactions with the clay exchange complex (interlayers or edge sites of clay minerals) and is, in contrast, enriched in light isotopes. To understand Mg dynamics correctly and how Mg isotopes depend on silicate weathering pathways, a characterization of the different compartments of soils (bulk soil, clay fraction, exchangeable pool, dissolved Mg in soil solutions, vegetation) is necessary. Following this idea, Opfergelt et al. (2014) presented the main drivers of the Mg cycle in Icelandic soils. They highlight the major role played by the soil exchange complex on the export of heavy Mg isotopes out of the soil profile or on the preferential uptake of heavy Mg isotopes by vegetation. This study is a perfect example of the use of Mg isotopes as a proxy to identify the complex interplay between biotic and abiotic mechanisms on the fate of a nutrient in soil.

Influence of organic matter complexation in the soil profile

The formation of metal–organic complexes represents another possibility for metal isotopes to fractionate due to thermodynamic differences in the bonding environment. Isotope effects associated with metal binding to organic matter are of particular interest in soils, particularly for tracing pedogenetic processes, such as podzolization. To illustrate the identification of organo–metallic complexation, we focus on Fe isotopes (as $\delta^{57}\text{Fe}$) since iron mobility can be significantly increased by organo–metallic complexes in soils, namely podzols.

Podzol formation is controlled by acid weathering and vertical translocation of Fe in the soil profile, together with Al, by organic matter complexation. Podzols cover around 485 million ha worldwide, mainly in the temperate and boreal regions of the Northern Hemisphere but are also present in humid temperate climates and in the humid tropics. During podzolization, Fe-bearing minerals are dissolved and Fe is translocated and enriched in the subsoil under the influence of organic ligands. Such iron–aluminum–organic complexes are then transported vertically downward until they re-precipitate in the B horizon. All these processes may induce Fe isotope fractionation. By comparing the isotopic composition of Fe in two soil profiles (Podzol and Cambisol), Wiederhold et al. (2007a) were able to specify the isotope fractionation of iron associated with the process of podzolization (i.e. complexation of Fe by organic acids and translocation of Fe in a complexed form), in generally oxidizing conditions, which therefore suppresses the redox effect. At the scale of the podzolic profile, a significant enrichment of Fe content is observed in Bh and Bs horizons while a depletion characterizes the overlying bleached A/E horizons. Systematic lighter $\delta^{57}\text{Fe}$ in B horizons and heavier $\delta^{57}\text{Fe}$ in A/E horizons are linked to the preferential translocation of light Fe isotopes complexed by dissolved organic matter, but also to the formation of poorly crystalline Fe oxides (Fekiacova et al., 2017). The Fe content in the Cambisol is roughly homogeneous and characterized by slight or moderate weathering of parent material and by the development of brownish colors in the Bw horizon due to the weathering of primary silicate minerals. The release of ferrous iron (Fe^{II}) is further oxidized and precipitated as iron oxide minerals. The variation of $\delta^{57}\text{Fe}$ is limited with depth, in accord with pedogenesis under oxic and well-drained conditions which involves neither transformations of Fe bearing minerals nor Fe translocation.

The previous two sections have shown how the isotopic effects of complexation, sorption, or interactions with plants and microorganisms can potentially overlap in soils. To identify organic complexation in soils, it was thus crucial to quantify its intrinsic isotope fractionation. However, separating free and organic-complexed species without inducing artifacts of isotope fractionation during the separation procedure is experimentally difficult. Among the various methods used to decipher the effect of metal complexation on isotope fractionation, the Donnan-membrane method coupled to thermodynamic modelling was successfully used for Cu and Zn isotopes (see Jouvin et al., 2009 and Ryan et al., 2014 in Moynier et al., 2017). For the latter, a strong isotope fractionation was observed, varying with pH and the type of binding site (low-affinity such as phenolic groups vs high affinity such as carboxylic groups). Heavy isotope enrichments were observed for Zn bound to a purified humic acid in comparison with free Zn^{2+} ions due to their stronger binding environments (e.g. Komárek et al., 2021).

Redox influence on pedogenesis

With silicate weathering and organic complexation, redox processes are responsible for the structure of soils and the redistribution of elements between and within soil horizons and or soil solutions. To determine the magnitude of redox processes in soils, isotope signatures of redox sensitive elements (e.g. Fe or Cr) have now been applied for 15 years. Important investigations were inevitably directed to iron isotope systematics, a major element which can be found as Fe^{II} or Fe^{III} species in soils. Large isotope fractionations (up to 3‰ between Fe^{III} -oxide and aqueous Fe^{II}) were determined for abiotic or biotic redox processes through comprehensive laboratory experiments (see the overview in Wu et al., 2019) with enrichment in light Fe isotopes in Fe^{II} species and heavier ones in Fe^{III} species. However, the variation in iron isotope signatures in bulk soils is surprisingly limited ($\delta^{57}\text{Fe}$ from -0.4 to 0.5‰ , Wu et al., 2019). The occurrence of simultaneous processes (oxidation, reduction, adsorption, organic complexation) and the kinetic vs equilibrium nature of isotope fractionation can explain this difference between laboratory and environmental conditions. Clearly, the use of Fe isotopes as tracers of redox processes depends on the type of soils. In well aerated soils such as Cambisols or Ferralsols, $\delta^{57}\text{Fe}$ is not modified compared with the bedrock value. It is associated with the poor mobility of dissolved iron in solution under these conditions and the quantitative in situ precipitation of iron as oxides and hydroxides (see Poitrasson et al., 2008 in Poitrasson, 2017; Wiederhold et al., 2007a). The variation of $\delta^{57}\text{Fe}$ in podzols was explained in the previous section as the effect of organic ligand control on chemical weathering and on the translocation of Fe species between illuviated and eluviated horizons. In waterlogged or redoximorphic soils (e.g. Gleysols), significant Fe isotope fractionation is associated with alternating oxidizing and reducing conditions, which enhances Fe mobility as Fe^{II} during periods of anoxia (see review of Wu et al., 2019). In these soils, the weathering of primary minerals or iron oxides is redox-controlled and is monitored through the release of light Fe^{2+} in solution and subsequent enrichment of the residual fraction in heavy isotopes. The reduced Fe then migrates and can leave the system, be adsorbed on oxides or be precipitated as oxides or hydroxides in deeper horizons with a depleted $\delta^{57}\text{Fe}$ value compared to that of topsoils (e.g. Wiederhold et al., 2007b). This depleted $\delta^{57}\text{Fe}$ in amorphous or crystalline oxides in comparison with Fe in the silicate phases has also been noted at the centimeter scale within a soil profile with homogeneous bulk $\delta^{57}\text{Fe}$ (Fekiacova et al., 2021). The low $\delta^{57}\text{Fe}$ contained in Fe—Mn oxides and the resulting high $\delta^{57}\text{Fe}$ in clays show that, within a soil profile where Fe mobility seems reasonably static, redox processes can occur efficiently and redistribute Fe between different carriers at the centimeter or micrometer scale.

Due to the complex geochemistry of iron and its limited isotope variation in soils, other tracers such as Cr isotopes ($\delta^{53}\text{Cr}$ hereafter) were recently developed to track the oxidation process in recent soils and paleosols with the goal to date the beginning of oxygenation of the Earth's atmosphere (see review of Wei et al., 2020). Chromium is mostly present in rocks and soils as Cr^{III} (chromite FeCr_2O_4 being the main Cr^{III} mineral), but it can be oxidized as Cr^{VI} by Mn oxides or hydrogen peroxide (details in Liang et al., 2021). Oxidation and partial reduction of Cr induce large isotope fractionation (Ellis et al., 2002), releasing heavy Cr^{VI} in solution and retaining a light $\delta^{53}\text{Cr}$ in residual solids. To date, although the number of studies is scarce, most modern and ancient weathering profiles report negatively fractionated $\delta^{53}\text{Cr}$ in accord with the oxidative mobilization of Cr. The absence of variation in soil $\delta^{53}\text{Cr}$ can also be useful because it should be either a diagnostic of acid dissolution without a redox process if Cr depletion is severe (Berger and Frei, 2014) or of a too-limited weathering intensity if chromium's depletion is minimal (e.g. Wille et al., 2018).

Control of pedological processes on trace metal behavior

In section “Isotopes and pedogenetic processes,” we highlighted the use of isotope ratios to identify the main pedological mechanisms that occur in soil, impacted by variation in mineralogy, redox or climatic conditions. Here, we will identify the main pedological processes controlling the mobility and speciation of trace metals through variation in their isotope signatures in soils. Reference reviews provide excellent summaries of the metal isotope fractionation occurring during chemical (adsorption, oxidation, organic complexation, precipitation) or biological (uptake) reactions (Komárek et al., 2021), which must be clearly identified prior to their use as non-traditional isotope systems for tracers in the environment (Wiederhold, 2015). In this chapter, we illustrate the effect of pedological processes on the dynamics of two trace metals, Cu and Zn, which present two clear advantages. First, experimental isotope fractionations associated with the main processes occurring in soils are well identified and second, the number of studies reporting isotope signatures for Cu (as $\delta^{65}\text{Cu}$) and Zn (as $\delta^{66}\text{Zn}$) in soils have increased considerably during the last 10 years allowing a comprehensive survey of their behavior in soil.

In the vast majority of cases, precipitation of secondary silicate minerals (e.g. clays) from primary minerals does not induce significant isotope fractionation for Zn and Cu incorporated in their crystalline structure (e.g. Little et al., 2019). In soil developed in tropical climates, metal sorption on clays is largely inhibited by acidic pH. This apparent limit is in reality useful to identify the two main mechanisms inducing Zn and Cu redistribution through soil profiles and fractionation of Cu and Zn isotopes: organic complexation and oxide adsorption/coprecipitation (Vance et al., 2016).

During pedogenesis, Cu and Zn depletions (expressed as τ_x values in Fig. 2) occur through their release from bedrock to soil solutions and they are often associated with an enrichment in light isotopes in the secondary minerals. Based on a synthesis of most $\delta^{65}\text{Cu}$ and $\delta^{66}\text{Zn}$ reported in soils, Vance et al. (2016) and more recently Little et al. (2019), explained this evolution by the partitioning of Cu and Zn isotopes between two main reservoirs. With the affinity of both metals to organic ligands, a pool of heavy Cu and slightly heavy Zn isotopes is complexed during or more likely after mineral dissolution and exported out of the system as colloids or organic particles in the soil solution. This process is supported by laboratory experiments (details in Moynier et al., 2017). In addition, the greater reactivity of Cu than Zn to organic ligands is consistent with the most severe depletion of heavy Cu during weathering and soil formation (negative $\Delta^{65}\text{Cu}_{\text{soil-parent_rock}}$ for lower τ_{Cu}) than for Zn isotopes (Fig. 2 and details in Moynier et al., 2017). The residual fraction, de facto enriched in light isotopes, is associated with iron and manganese oxy-hydroxide as adsorbed or internalized species. The process involved between adsorption and coprecipitation is still debated as experimental sorption of Cu and Zn on Fe and Mn oxides enriches the mineral surface in heavy isotopes (details in Komárek et al., 2021), in contradiction with natural observations. The preferential complexation of Cu and Zn by organic ligands can partly explain scavenging of the complementary light pool by oxide surfaces. However, recent studies developed on lateritic tropical profiles, suggest that incorporation of Cu and Zn rather than adsorption could have caused light isotope enrichment in oxides during 'ferrugination' through kinetic isotope control (details in Little et al., 2019), even if experimental isotope fractionation

Fig. 2 Evolution of integrated isotope compositions with integrated τ_x for soil profiles. The integrated Cu and Zn isotopes in soils are reported as the deviation between weathered soil profiles and the parent material ($\Delta^{65}\text{Cu}_{\text{profile}} = \delta^{65}\text{Cu}_{\text{int_soil}} - \delta^{65}\text{Cu}_{\text{parent_rock}}$ and $\Delta^{66}\text{Zn}_{\text{profile}} = \delta^{66}\text{Zn}_{\text{int_soil}} - \delta^{66}\text{Zn}_{\text{parent_rock}}$). The integrated τ_x is defined using depth, invariant element (Nb (niobium), Zr (zirconium), Ti (titanium) or Al depending on the study) and soil density when available. This figure updates the previous compilation published in Little SH, Munson S, Prytulak J, Coles BJ, Hammond SJ, and Widdowson M (2019) Cu and Zn isotope fractionation during extreme chemical weathering. *Geochimica et Cosmochimica Acta* 263: 85–107.

during Cu and Zn incorporation in oxides is currently unknown. This complex interplay between organic matter and oxide controls in soils has recently been illustrated for Zn in Icelandic soils (Opfergelt et al., 2017). In this area, the light isotope enrichment observed during pedogenesis is not coupled with the total organic carbon but with the plant-derived organic pool that has been preserved from decomposition through organo–mineral association, typically iron oxides.

To summarize, in soils, the control of Cu and Zn speciation and dynamics by the organic compartment is dominant while immobilization on or in oxides seems secondary. The primary control of organic material is even emphasized in topsoil. In these organic-rich O horizons that can be partially decoupled from the lower part of the soil, the light isotope signatures are mostly associated with the mineralized organic debris of the aboveground vegetation. Enrichment in light Cu and Zn isotopes has been observed in most of higher plants through processes of biological uptake and Cu reduction during assimilation (details in Moynier et al., 2017). Finally, under extreme weathering conditions, demobilization of iron oxides can cause severe Cu and Zn depletion ($\tau_X < -0.8$, Fig. 2). The associated shift toward higher $\delta^{65}\text{Cu}$ and to a lesser extent $\delta^{66}\text{Zn}$ is presumably linked with allochthonous Cu and Zn inputs as atmospheric dust (Vance et al., 2016).

Tracing the source of metal pollution in soils

Soil pollution is one of the relevant threats known to affect soil quality, and in a broader extent human health, food quality, as well as soil biodiversity and water quality. At high content, most metals can be seen as contaminants in soils, mainly due to anthropogenic activities. Metal isotopes can be used to trace the source of the contamination and the number of studies has increased rapidly during the past 15 years. To illustrate the potential that metal isotopes can have to fingerprint the origin of metals in human-impacted environments, we focus on two isotope systems, Pb and Zn.

Lead is one of the main and oldest pollutants of anthropogenic origin, whose origin can be associated with mining, metallurgy, batteries, pigments, ceramics, burning fossil fuels, sludge or treatment plants. Lead has four stable isotopes; three radiogenic: ^{208}Pb (52%), ^{206}Pb (24%), ^{207}Pb (23%) and one non-radiogenic: ^{204}Pb (1%). The isotope composition of Pb is expressed in the form of ratios: e.g. $^{206}\text{Pb}/^{204}\text{Pb}$, $^{206}\text{Pb}/^{207}\text{Pb}$, $^{208}\text{Pb}/^{206}\text{Pb}$. Lead isotopes are commonly used to differentiate anthropogenic Pb inputs from the geochemical background (i.e. geogenic Pb) in soils. They also make it possible to follow the dynamics of Pb in the soil, i.e. its accumulation on the surface of the soil in the litter, or on the contrary, to highlight the pedogenetic control on Pb migration within deeper mineral or organo–mineral horizons (Podzol). By studying the isotopic composition of Pb in two soil profiles (Andosol and Podzol) representative of undisturbed ecosystems and located far from pollution point sources, such as cities, main roads, and industries, Semlali et al. (2001) were able to highlight the strong contribution of anthropogenic Pb in soil litter and A horizons relative to geogenic Pb. With the $^{206}\text{Pb}/^{207}\text{Pb}$ isotopic ratio, they demonstrated that the exogenous/anthropogenic Pb mainly came from historical pollution ($^{206}\text{Pb}/^{207}\text{Pb}$ value 1.16–1.18) linked to the use of Pb ores, rather than pollution linked to automobile activity (leaded gasoline in France had $^{206}\text{Pb}/^{207}\text{Pb}$ ratios from 1.069 to 1.094) or industrial activity ($^{206}\text{Pb}/^{207}\text{Pb}$ ratios varied from 1.143 to 1.155). Andosol pedogenesis is characterized by hydrolysis of volcanic material and neoformation of short-range order minerals such as allophane and imogolite, intimately associated with organic matter. Together, organic matter and short-range order minerals contribute to high Pb retention in the profile, and exogenous Pb accumulates in organic matter rich horizons, i.e. topsoil. Pedogenesis in podzols (i.e. strongly weathered and acid soils, developed on well-drained substrates), is controlled by organic acids produced in the litter that act as strong weathering and metal-complexing agents. Anthropogenic Pb is dominant in litter horizons, but is also found in Bh horizons of the Podzol in humus coatings on mineral grains, due to the migration of Pb associated with colloidal organic matter.

Road activity is also a main source of contamination of soils located near highways, due to the presence of Pb in gasoline until its exclusion in the 2000s. Walraven et al. (2014) clearly demonstrated the effect of leaded gasoline on soils near two highways in The Netherlands, in which Pb accumulated in the top 15 cm of the soil associated with organic matter. This exogenous fraction of Pb in soils is often more mobile and bioavailable than geogenic Pb and can contribute to Pb contamination of groundwater. The migration of Pb in acidic soils with low reactive mineral content reduces Pb retention (Walraven et al., 2014). This high content of available Pb can also be a source of contamination to aboveground plants (Chrastny et al., 2010).

If highly concentrated, zinc can also become a pollutant in soils with various origins: sewage sludge and pig slurry spreading, vehicle emissions and road runoff, industrial and smelter emissions. Zinc isotopes ($\delta^{66}\text{Zn}$), together with Zn solid speciation have been investigated along two soil profiles sampled near one of the largest Pb and Zn processing plants in Europe in northern France (Juillot et al., 2011). The two soils studied show large Zn contents in topsoils (570 to 1380 mg kg⁻¹) which decrease markedly with depth to around 50 mg kg⁻¹, close to the regional Zn geochemical background. Spectroscopic investigations have shown that Zn occurs in the form of franklinite-bearing slag grains originating from processing wastes in the upper soil horizons, while Zn-bearing illite is the main geogenic Zn-containing species. The $\delta^{66}\text{Zn}$ values in the mineral horizons (mean value $0.31 \pm 0.38\text{‰}$) are interpreted as being representative of the local geochemical background, whereas heavier $\delta^{66}\text{Zn}$ values near the surface of the two soils ($0.38 \pm 0.45\text{‰}$ to $0.76 \pm 0.14\text{‰}$) are related to anthropogenic Zn in line with the smelter waste signatures ($\delta^{66}\text{Zn}$ values of $0.81 \pm 0.20\text{‰}$) from the vicinity of the processing plant. It is thus possible to use Zn isotopes to fingerprint Zn sources in smelter-impacted soils. However, the lighter $\delta^{66}\text{Zn}$ measured in the surface horizons compared to that in the slag can also result from an isotope fractionation resulting from pedogenetic bio-physicochemical processes, showing the need to combine isotope approaches with other proxies such as solid speciation analysis.

Conclusions and reflections

The use of non-traditional stable isotope systems in environmental geochemistry is a fast-developing scientific field. Even if the determination of intrinsic isotope fractionation in the laboratory during complexation, biological uptake, adsorption or precipitation reactions has been developed for some isotope systems (“isotope fractionation black box”), efforts must be continued to remove barriers preventing application of isotope systems in the Critical Zone. Theoretical approaches (e.g. ab initio calculations) can also help in understanding mechanisms of fractionation at the molecular scale. This chapter has shown that the use of metal stable isotopes in soils is a powerful tool. Identification of weathering processes and of the main physicochemical processes affecting metals in soil can also be facilitated by tracing the pollution source in human-impacted environments.

Finally, it must be noted that this chapter focusses on abiotic processes. Soil contains a large variety of habitats and nutrients, and many living organisms (plants, bacteria, fungi, invertebrates) are present. They contribute to the recycling of organic matter, mineral weathering, the modification of water flow, and to metal cycling. Studies have shown that metals can be fractionated by biological processes, which are governed by the same physical and chemical principles as abiotic processes, as described above (see for instance Wiederhold, 2015; Poitrasson, 2017; Moynier et al., 2017; Bouchez et al., 2013). Understanding of the complex interplay between abiotic and biotic control on metal dynamics is still at the beginning and it represents an exciting research avenue for the Critical Zone community.

Abstract

The current chapter focuses on potassium (K) and sodium (Na) of the alkali metals following their central role in agricultural soils. The former is an essential plant macro-nutrient and accumulation of the latter in soils often results in degradation of soil structure and associated physicochemical, physical and hydraulic properties. In soil, K is present mostly in the structural pool (90%), while the K ion in the soil solution is just 1 to 2% of the soil K pool, yet it is the most available form for plants. Sodium is, in general, the dominant alkali cation in soils. Productivity in Na-affected (sodic) soils is limited because of deterioration in the physical properties, crop tolerance to Na per se and plant nutrition in Na-affected soils.

Key points

- Potassium and Sodium belong to the alkali metals group and play a central role in agricultural soils.
- Potassium ion in the soil solution is the most available form for plants.
- Potassium availability in soils for plants is best estimated based on the concept of quantity (Q) and intensity (I).
- Productivity of Na-affected (sodic) soils is limited.
- Sodic soils rehabilitation may positively affect C cycle and accumulation in soils.

The alkali metals

Group 1A in the Periodic Table comprises the elements lithium (Li), sodium (Na), potassium (K), rubidium (Rb), cesium (Cs) and francium (Fr) that are commonly referred to as Alkali metals. In soils, all these elements, but for Fr, exist in the form of stable isotopes. Conversely, only the radioactive isotope ^{223}Fr occurs naturally but it is rather difficult to find in soils. Readers interested in an in depth discussion on the alkali metals are referred to the review by Scott and Smith (1987) and references cited therein.

In brief (with no reference to Fr), the alkali metals share the same outer electron configuration, and in soils they are reactive and form monovalent cations and soluble salts. Yet, they differ in numerous characteristics, as well as, in their relative abundance and quantity in soils (Table 1).

A chapter containing a detailed discussion on the cation exchange complex of soil solid components (clays, oxides, organic matter) is included in this Encyclopedia. Readers interested in sources of the surface charge of soil particles, and theory of the distribution of ions between the charged surfaces and the soil solution, and the theories of cation exchange are referred to that chapter. The distribution of the alkali metals between the solution and cation exchange complex of the above-mentioned soil solid components has a strong effect on their mobility in soil, on soil structural stability and availability to plants. Therefore, here we present briefly the factors affecting the exchange of the alkali metals with each other and with the dominant divalent cations (Ca^{+2} and Mg^{+2}). The two main factors controlling the binding strength of the charged surface for a specific cation according to the theory of the diffuse double layer charge are the valence and the hydrated radii of the cation. The binding strength of cations increase as a function of the valence, trivalent > divalent > univalent. All the alkali metals are univalent, hence this factor is identical in their binding strength. Consequently, the hydrated radii of the cations is the main factor determining the order of their binding strength, which decreases as the hydrated radii increases. From the values of the hydrated radii (Table 1) we can derive the following order of

Table 1 Characteristics and relative abundance (atoms per 10^6 Si atoms) and quantity of the alkali elements in soils.

	<i>Li</i>	<i>Na</i>	<i>K</i>	<i>Rb</i>	<i>Cs</i>
Atomic number	3	11	19	37	55
Atomic weight	6.939	22.9898	39.102	85.49	132.905
Ionic potential	1.32	1.02	0.75	0.68	0.60
Electronegativity	0.95	0.9	0.8	0.8	0.75
Hydrated radii (nm)	0.340	0.276	0.232	0.228	0.228
Hydration energy (kJ mol^{-1})	519	406	322	293	264
Relative abundance in soil	346	21,900	28,600	141	3
Quantity in soils (mg kg^{-1})	26	6200	14,000	140	5

binding strength for the alkali metals: $\text{Cs}=\text{Rb}>\text{K}>\text{Na}>\text{Li}$. As the relative abundance of Na and K in soil is of the same order and is much higher (2 to 4 orders of magnitude) than the other alkali metals, this suggests that the exchange complex of soils has a greater affinity for K than for Na. A quantitative estimate of a nearly seven times greater affinity of soils for K over Na is presented in the report of the **US Salinity Laboratory (1954)**.

Naturally occurring lithium appears in the form of two stable isotopes, ^6Li and ^7Li , the latter being the more abundant (92.5% natural abundance) (Krebs, 2006). Lithium has a distinct involvement in soil-forming reactions; stable isotopic analyses of Li help to gain insight into the mechanisms and rates governing the transfer of matter from bedrocks to surface waters. Thus, Li isotopes are a powerful tool for understanding the processes leading to clay mineral formation in soils. Yet, no plant induced Li isotopic fractionation has been recorded, possibly due to its very low concentration in vegetation; it is three orders of magnitude less than that in soil (Schmitt et al., 2012). From the agricultural perspective, Li is not considered an essential plant nutrient, possibly due to its very low concentrations ($<100 \text{ mg kg}^{-1}$) in soils; yet, Li may have toxic effects on plants, especially citrus. Moreover, concentration of $<5 \text{ mg L}^{-1}$ of Li in irrigation water may lead to harmful effects on some plants. However, there are also reports on the beneficial effects of Li on plant growth and subsequently on human health through the food chain (Scott and Smith, 1987 and references cited therein).

Rubidium has two naturally occurring radioactive isotopes, ^{85}Rb (72.2%) and ^{87}Rb (27.8%) with a half-life of 48.8×10^9 years. Rubidium is the 20th most abundant element in the Earth's upper continental crust. The Rb geochemistry is closely related to that of potassium. Rubidium does not form its own minerals but, due to similarity of the ionic radii (Table 1), it can substitute for K in mica and K-feldspar, as well as in rarer minerals, like lepidolite or carnallite. Limestone has small concentrations of Rb (4 mg kg^{-1}), while granite and pegmatite usually have large Rb concentrations (e.g. 120 mg kg^{-1} in granite) as do some sedimentary rocks (140 mg kg^{-1}). Furthermore, it is generally assumed that Rb, after being dissolved during weathering, is adsorbed more strongly by the clay fraction of soils than potassium (Goldschmidt, 1954, in Negrel et al., 2018). Rubidium has very few applications and is mostly used in research, e.g., dating of geological materials using ^{87}Rb , photocells and some pharmaceuticals (e.g., as an antidepressant like Li). Glass dust could be one possible source of Rb transfer to the environment. An additional source of contamination to soils and the environment is the radioactive isotope ^{86}Rb from radioactive fallout; yet its short half-life time (18.6 days) lessens its importance in soils (Scott and Smith, 1987). In agricultural soils, Rubidium is considered as non-essential and non-toxic; it is easily taken up together with K being its associated trace element (Negrel et al., 2018).

Cesium, is the heaviest (nearly 1.6 as heavy as Rb) alkali metal with an estimated small abundance in the upper continental crust of 5 mg kg^{-1} (Table 1). There are however geochemical differences in its spatial distribution; Cs concentration in soils of northern Europe is two times lower than in those of southern Europe. Cesium forms some very rare minerals (e.g., pollucite) and often substitutes for K in mica (especially in muscovite and lepidolite) and in K-feldspar, and is enriched in felsic rocks during magmatic fractionation, with pegmatite having the largest Cs concentrations. With its high volatility, Cs tends to concentrate in the late stages of magmatic differentiation and in sublimates of K-rich volcanic rocks in active volcanic regions. Among sedimentary rocks, Cs concentrations are low in limestone and high in shale and schist. In a silicate environment, most Cs is transferred to the weathering fraction, similar to Rb, and is subsequently enriched in the clay fraction. The mobility of Cs in soil is therefore low, because it strongly adsorbs to the clay material. The strong affinity of Cs for weathering products (i.e., clay minerals) causes considerable fractionation of this element during the chemical weathering of rocks (Negrel et al., 2018 and references cited therein). Cesium is more toxic to plants than Rb, but less so than Li when absorbed at large concentrations, although this rarely occurs under natural environmental conditions.

Compared with the aforementioned alkali metals, K and Na have received far more attention as the former is an essential plant macro-nutrient and accumulation of the latter in soils often results in degradation of soil structure and deterioration of its physico-chemical, physical and hydraulic properties. Following the central role of K and Na in agricultural soils, therefore, each is discussed further in detail below.

Potassium in soils and plant nutrition

Potassium in soils

There are 25 known **isotopes** of potassium, three of which occur naturally: ^{39}K (93.3%), ^{40}K (0.0117%), and ^{41}K (6.7%). Naturally occurring ^{40}K has a **half-life** of 1.250×10^9 years. It decays to stable ^{40}Ar (argon) by **electron capture** or **positron emission** (11.2%) or to stable ^{40}Ca by **beta decay** (88.8%) (Audi et al., 2003). The decay of ^{40}K to ^{40}Ar is the basis of a common method for dating rocks. **Minerals** are dated by measurement of the concentration of K and the amount of radiogenic ^{40}Ar that has accumulated. The minerals best suited for dating include **biotite**, muscovite, metamorphic **hornblende**, and volcanic **feldspar**. Apart from dating, K isotopes have been used as **tracers** in studies of **weathering** and for **nutrient cycling** studies because K is a **macronutrient** required for the complete **life cycle** of the plant (Kirkby, 2012).

Potassium is a univalent cation with a hydrated ionic radius of 0.331 nm and a hydration energy of 314 J mol^{-1} . Potassium is the most abundant alkali metal in soil (Table 1). It is distributed between the following pools in the soil: structural, fixed (non-exchangeable), exchangeable, soluble, organic matter and microbial K (Fig. 1).

The potassium ion in the soil solution is the most available form for plants. However, just 1 to 2% of the soil K is in this pool. Over 90% of soil K is in the structural pool, mainly in micas and feldspars. Its rate of release to the soil solution and the exchangeable and fixed fractions is a very slow process, at a time scale of years; therefore, it is defined as unavailable to plants. However, these minerals affect long term soil fertility serving as large pools of potassium that replenish its depleted labile pools (Barber, 1995). Fixed (non-exchangeable) K is the second largest pool in soils and a considerable amount occurs in the secondary minerals of the mica group, and the vermiculite and Illite clay minerals. Fixed K is different from structural K (Rich, 1968) in that it is not bound within the crystal structures of soil minerals, but is held at the interlayer space of weathered micas, vermiculites, and hydroxyl-interlayered vermiculites (Fig. 2).

Fig. 1 A schematic diagram of the K cycle in soil including input, output and losses.

Fig. 2 Proposed model of an expandable layer silicate with interlayers indicating the effect on K fixation. Reproduced with permission from Rich CI (1968) Mineralogy of soil potassium. In: Kilmer VJ, Younts SE, and Brady NC (eds). *The Role of Potassium in Agriculture*. Madison, WI: American Society of Agronomy, Crop Science Society of America, and Soil Science Society of America.

Potassium becomes fixed because the binding forces between K and the mineral surfaces are greater than the hydration forces between individual K ions. Fixed K results in a partial collapse of the crystal structures and the K ions are physically trapped to varying degrees, making K release a slow, diffusion-controlled process. Fixed K can be replaced with ammonium (NH_4) which has a similar hydrated radius, yet larger hydrated cations like Ca, Mg and Na cannot fit into the space of the interlayers.

The release of fixed K to the soil solution is controlled by diffusion. The rate of release of fixed K to the soil solution and the exchangeable pools is much faster than that of the structural K, but much slower than exchangeable K. The contribution of the fixed K pool to K uptake by plants depends on soil properties, environmental conditions, soil water content, transpiration, root size and architecture (Barber, 1995). The exchangeable K pool is much larger than the soluble pool and thus is the main source of K to plants because of the very large exchange rate of K between the soil solution and the cation exchange complex (less than a millisecond) (Bar-Tal et al., 1995). Removal of K from the soil in the root zone includes uptake by plants and removal with harvested plant biomass, and K losses by downward leaching, soil erosion and runoff. A practical implication of the strong preference for K adsorption over Na is the limited mobility of K by leaching and the distribution of K in the soil profile following K fertilizer input and or irrigation water containing K. In clay soils, K accumulates in the top layer with decreasing concentration with depth, while in sandy soils there is a more uniform distribution of K with soil depth.

Addition of K to agricultural soils is mainly by fertilizers, manures and other organic wastes, and irrigation water. Note that when organic wastes are applied to soil most of the K in the organic matter is in inorganic form that becomes available in the soil solution. Nevertheless, a small fraction is consumed by the growing microorganisms that decompose the waste and produce soil organic matter. The dose of applied manure to cultivated lands is determined mainly by its nitrogen content, therefore, when manure rich in K is used, large amounts of K accumulate in the soil. Unharvested plant residues are also decomposed in the soil by microorganisms, which release K ions to the soil solution. The fraction of microorganism-derived K in the whole soil system is <1%, but it plays an important role in the cycling of K between the organic and inorganic pools, although it is much less important than in the cycles of nitrogen, sulfur and phosphorus.

Potassium effects on soils structure and physical properties

The impact of K on soil physical and hydraulic properties has received much less attention than that of Na. Moreover, research on K has yielded varying and at times conflicting results. Soil permeability has been reported to decrease in relation to the different exchangeable cations in the following order $\text{Ca} > \text{Mg} > \text{K} > \text{Na}$ (Arienzo et al., 2012). Some studies have reported that K can be considered equivalent to Na regarding its negative impact on soil physical properties, yet, other studies have noted larger aggregates with greater stability (Bronick and Lal, 2005) and hydraulic conductivity (HC) in K saturated soils than in those saturated with divalent cations. In addition, Levy and Torrento (1995) observed for a loamy sand and a sandy clay, that increasing exchangeable potassium percentage (EPP) up to 15% did not have an adverse effect on soil susceptibility to clay dispersion and aggregate breakdown. Chen et al. (1983) noted that the effect of exchangeable K on soil HC depended on soil type; in a clay and a loamy sand the HC increased up to 20 times with increases in EPP up to 20, and thereafter decreased following an additional increase in EPP. In a sandy clay the HC decreased uninterruptedly with an increase in EPP above 5.8 (Chen et al., 1983). In addition, irrigation with water containing large concentrations of K ($\sim 120 \text{ mg L}^{-1}$) led to a decrease of 80% in the permeability of a sandy loam (Peacock, 2007). Shainberg et al. (1987) suggested that the swelling of K-smectites depends on the charge density of the clay (i.e., the ratio of clay CEC to its specific surface area; the lower the charge density, the greater the swelling). The charge density of montmorillonitic clay can vary between 1.05 and $2.25 \text{ mol}_c \text{ m}^{-2} \times 10^{-6}$. A value greater than 1.3 has been considered to represent a clay with a high charge density (Shainberg et al., 1987). More recently it has been suggested that these conflicting results with respect to the effects of exchangeable K on soil physical and hydraulic properties could, at least in part, be ascribed to differences in soil mineralogy. In predominantly kaolinitic or illitic soils, the effects of K are likely to be either similar to those of Na or intermediate between those of Na and Ca, while in predominantly smectitic soils the effects of K and Ca are likely to be comparable.

Potassium in plant nutrition

Potassium uptake is highly selective and closely coupled to metabolic activity (Hawkesford et al., 2012 and references cited therein). It is characterized by high mobility in plants at all levels – within individual cells and tissues, also in long-distance transport via the xylem and phloem. Uptake and transport of K throughout the plant is facilitated by integral membrane proteins (transporters and cation channels) which enable its movement across the plasma membrane. Potassium is the most abundant cation in the cytosol, and K and its accompanying anions contribute substantially to the osmotic potential of cells and tissues of glycophytic plant species. For various reasons, K has an outstanding role in plant–water relations (Hawkesford et al., 2012 and references cited therein). Potassium is not metabolized and it forms only weak complexes in which it is readily exchangeable (Hawkesford et al., 2012 and references cited therein). Therefore, K does not compete strongly for binding sites of divalent cations (e.g., Mg). On the other hand, due to its large concentrations in the cytosol and chloroplasts, it balances the charge of soluble (e.g., organic acid anions and inorganic anions) and insoluble anions and thus facilitates the stabilizing of pH between 7.0 and 8.0 in these compartments, which is the optimum for most enzyme reactions.

Potassium availability

Estimation of K availability in soils is based on the concept of quantity (Q) and intensity (I). A detailed description of this concept with regard to K availability in soils can be found in numerous reviews (e.g., Huang et al., 2005 and references cited therein). In brief, the quantity (Q) of labile K in soil for plant consumption has been defined as the exchangeable K. A linear relationship between K uptake by plants and the quantity of exchangeable K was obtained in many pot and field studies. However, in other studies this relationship did not hold for some types of soil, in which an intensity (I) factor was found more useful. The intensity (I) of K in a soil at equilibrium with its solution could best be defined by the ratio $a_k/(a_{Ca}+a_{Mg})^{1/2}$ (where a is ion activity) of the soil solution. This equilibrium activity ratio for K, referred to as AR^K , is analogous to the Gapon equation which was developed for Na exchange in soils with the divalent cations, Ca and Mg. The AR^K was suggested by Woodruff (1955) as a measure of K availability. It has been proposed that the activity of K in the soil solution is of primary importance as it is central for K diffusion and K translocation in soils by mass flow to roots (Barber, 1995). Woodruff (1955) suggested a general energy expression of the intensity factor using a natural logarithmic transformation of AR^K multiplied by the Boltzmann constant (R) and temperature ($T, ^\circ K$).

$$\Delta F = RT \ln(AR^K) \quad (1)$$

The larger are the values of labile K ($|\Delta F|$), the greater is the release of K into the soil solution, resulting in a larger pool of labile K.

Strong correlation ($r = 0.80$) between the (I) and (Q) parameters for available K were obtained in pot and field studies when the same soil or soils with similar properties were investigated under different management practices (Fig. 3). However, as can be seen from the data of Feigenbaum and Hagin (1967), soils with the same value of AR^K may have a wide range of capacity (Q) for maintaining AR^K under cultivation (Fig. 3). Therefore, other researchers (e.g., Beckett et al., 1964a,b in Sparks and Huang, 1985) suggested use of the classic Q/I relationships where the activity ratio AR^K value is related to the change in exchangeable K to obtain the effect of the quantity of labile K (exchangeable K) on the intensity of labile K (AR^K). In general, it appears that the Q/I concept is a good measure of the availability of the more labile K in soils to plants. The method used for constructing a typical Q/I curve involves equilibrating a soil with solutions containing a constant concentration of $CaCl_2$ (calcium chloride) and increasing the concentration of KCl (potassium chloride). The AR^K values are then plotted versus the gain or loss of K to form the characteristic Q/I curve (Sparks and Liebhardt, 1981) (Fig. 4).

Several parameters can be obtained from the Q/I plot to characterize soil K status. The value of AR^K when the Q factor (ΔK) equals zero is a measure of the degree of K availability at equilibrium or AR_c^K . The value of ΔK when AR^K equals zero is a measure of labile or exchangeable K in soils or ΔK^0 . The slope of the linear portion of the curve gives the potential buffering capacity of K (PBC^K) and is proportional to the cation exchange capacity of the soil.

The PBC^K indicates the ability of a soil to maintain the intensity of K in the soil solution. A large PBC^K value indicates constant availability of K in the soil over a long period. By contrast, a small PBC^K value would indicate the need for frequent K fertilization. Cropping, fertilization and application of soil amendments can change the PBC^K values of soils (Sparks and Huang, 1985).

Fertilizer recommendations and effects on crops and soil

Fertilizer recommendations for K are based on two groups of methods: soil tests and plants data (Brouder et al., 2021). Various soil tests have been developed for recommendations of K fertilizer based on the estimation of exchangeable K as the Q factor or AR^K as

Fig. 3 Relationship between ΔF values and exchangeable K expressed as a percentage of soil cation exchange capacity. From Feigenbaum S and Hagin J (1967) Evaluation of methods for determining available soil potassium based on potassium uptake by plants. *Journal of Soil Science* 18: 197–203.

Fig. 4 Typical quantity/intensity (Q/I) plot. Reproduced with permission from Sparks DL and Liebhardt WC (1981) Effect of long-term lime and potassium application on quantity-intensity (Q/I) relationship in sandy soil. *Soil Science Society of America Journal* 45:786–790.

the intensity (I) factor. Although there were strong correlations between both types of parameters and K uptake by plants, in some soils there were many cases where no correlations were obtained. In some soils, in which non-exchangeable K contributes considerably to K uptake by plants, a combined estimate of both sources of K is used. However, the estimate of the relative contribution of non-exchangeable K is not straightforward and depends on complex factors including plant species, management, climate and soil moisture. Another limitation of both Q and I factors is that they signify whether the status of K in the soil, determined at a specific time, is above or below the threshold for fertilization, yet Q and I do not indicate the dose of K fertilizer that should be applied. The Q/I concept described above can be used to predict change in the amount of Q by change in I. A new method based on the Q/I concept was recently developed and tested in pot experiments with various soil types from Israel representing a wide range of properties including clay and lime contents, cation exchange capacity and specific surface area (Shenker and Seth, 2018). However, this method still needs to be tested in field experiments. It requires some additional data such as the optimal K consumption of a given crop in a specific region for an expected yield and the volume of soil supplying K. The main limitation of this method is economic because it requires measurements of exchangeable and soluble K, Ca and Mg at a wide range of K content in soil. Brouder et al. (2021) discuss in depth the gaps in knowledge for improving K fertilizer recommendations. They also discuss potential and required research for the use of mechanistic models of K release, exchange, movement in soil and uptake by plants, and machine learning models based on experimental data.

When reliable soil tests are not available and when there are no well-proved K fertilizer recommendations based on soil tests, there is the option to use recommendations based on plant data. Such recommendations depend on the assumption that K concentrations in soils should be maintained by a K fertilizer rate that replaces K removed by crop harvest. Long-term K fertilization affects clay mineralogy, including the transformation of Illitic clay to montmorillonite under little or no K fertilizer application and vice versa with large K fertilizer application (Sandler et al., 2009 in Bar-Yosef et al., 2015).

Plants' response to K supply or deficiency has been shown in many pot experiments and those of nutrient solutions. An example of the response of olive (*Olea europaea* L.) plants to K fertilizer application in a pot experiment of Erel et al. (2015) is shown in Fig. 5. However, the lack of response to K fertilizer in many field studies and surveys has raised the question of whether fertilization with K is beneficial for crop production (Bar-Yosef et al., 2015). Khan et al. (2014 in Bar-Yosef et al., 2015) presented evidence that soil exchangeable K increases over time without the addition of K to the soil despite its removal by crops in montmorillonitic and illitic soils. The authors termed this behavior 'The potassium paradox'. They also reported a lack of crop response to KCl fertilization. Bar-Yosef et al. (2015) showed that the observations of Khan et al. (2014 in Bar-Yosef et al., 2015) can be interpreted and predicted using current knowledge of K reactions in soil and its uptake by plants, and that there is no paradox in K behavior in the soil–plant system (for more details see Bar-Yosef et al., 2015). Moreover, Mueller et al. (2012) estimated that there should be an increase of 34% in global K fertilization to close global yield gaps to 75% of attainable yields, while eliminating overuse of inputs that may harm the environment.

Sodium in soils

A chapter devoted to Na-affected soils (Sodic Soils) is included in the Encyclopedia (Chapter XX). Readers interested in the effects of sodicity on soil chemo-physical, physical and hydraulic properties are referred to this chapter. The current chapter will focus mostly on the chemical and fertility effects of Na on soils.

Fig. 5 The response of olive plants to 6 months of exposure to irrigation solutions containing: 2.48 mM K and 2.84 mM Na (+K), or 0.08 mM K and 2.48 mM Na (+Na) or 0.09 mM K and 0.13 mM Na (–K –Na). Whole plant response and leaves. Upper row, adopted from Erel R, Ben Gal A, Dag A, Schwartz A, and Yermiyahu U (2014) Sodium replacement of potassium in physiological processes of olive trees (var. Barnea) as affected by drought. *Tree Physiology* 34: 1102–1117; lower row, Erel R, Yermiyahu U, Ben-Gal A, Dag A, Shapira O, and Schwartz A (2015) Modification of non-stomatal limitation and photoprotection due to K and Na nutrition of olive trees. *Journal of Plant Physiology* 177: 1–10.

Sodium is, in general, the dominant alkali cation in soils, especially in salt affected ones. Data compiled by Wansik et al. (2016) indicate that Na-affected soils cover 581 million ha worldwide, with the largest areas of Na-affected soils concentrated in Australia (340 million ha) followed by north-central Asia (120.1 million ha) South America (59.6 million ha), Africa (27 million ha), Europe (22.3 million ha) and North America (9.6 million ha). This spatial distribution of Na-affected soils demonstrates that they occur under a range of climates.

Commonly, the content of Na relative to that of the divalent cations (Ca and Mg) in the soil exchange complex and or the soil solution determines whether a soil is affected by Na or not (see Chapter XX). Yet, soil sensitivity to Na can also be evaluated from Na concentration in the soil solution relative to that of the main anions in the solution (Fig. 6). The data presented in this Figure indicate that once Na concentration is higher than or equal to that of the combined concentration of Cl^- and SO_4^{2-} , then the soil is adversely affected by Na.

Sodium and soil productivity

The productivity of sodic soils is limited, mainly because of the deterioration in their physical properties, which causes poor aeration, restricts root development and enhances root diseases. However, the impact of Na on soil productivity may also depend on crop tolerance to Na per se and plant nutrition in Na-affected soils. A detailed review on nutrient constraints in Na-affected soils is presented in Qadir and Schubert (2002).

Plant species are characterized as ‘natrophilic’ or ‘natrophobic,’ depending on their growth response to Na and their capacity to take up Na by roots and transport it to shoots (e.g., Phillips et al., 2000). The role of Na in plant nutrition in different species is: (i) essential for certain plant species, (ii) replacing K functions in plants at different concentrations, and (iii) a beneficial element enhancing growth (Broadley et al., 2012). Growth of many halophytes, whether C3 or C4 species, is enhanced by large Na concentrations in the substrate (generally, 10–100 mM Na, but up to 510 mM Na in extreme cases; Redondo-Gomez et al., 2010). However, the majority of commercial crops are defined as non-halophytes (glycophytes), therefore such large Na

Fig. 6 Graphic illustration of Na-affected soils (below the solid arrow and to the right of the solid part of the vertical and horizontal threshold line) vs. non Na-affected soils (left of the vertical threshold line). From Mapping Salt-affected soils. Technical Manual. FAO. Roma. 2020.

concentrations are not required. Sodium is not essential for C3 species but it is an essential micro-nutrient for many, but not all C4 species. In general, the concentration of Na in the soil solution of the majority of agricultural soils is much higher than that required for C4 species. Sodium was found as a proxy for K and can replace it under low K availability in several herbaceous plants (Kronzucker et al., 2013) and fruit trees (e.g. olives, Erel et al., 2014, Fig. 5).

Large Na concentrations were found to be toxic to many glycophytes plants, where the predominant effect of the co-presence of Na^+ in K^+ -containing media is one of affecting K^+ homeostasis negatively. More detailed description of the various aspects of sodium toxicity are presented in the review by Kronzucker et al. (2013). Typical symptoms of sodium toxicity are necrotic spotting in the leaves, followed by the development of a marginal necrotic band, as shown for an olive tree in Fig. 7.

Some research has indicated that most field crops are classified as moderately tolerant or tolerant to Na; yet some crops such as deciduous fruits, nuts (Juglandaceae), citrus and avocado (*Persea Americana* Mill.) may show signs of Na toxicity (Pearson, 1960). It should be born in mind, however, that ranking of crops for Na tolerance and nutrient constraints strongly depends on the environmental conditions under which the response was determined.

Fig. 7 Sodium toxicity symptoms in the tips of olive leaves in which Na concentration was 4 mg g^{-1} , compared with a threshold value of 2 mg g^{-1} . Courtesy of Dr. Ran Erel and Prof. Uri Yermiyahu.

Chemical problems in sodic soils relating to plant nutrition may range from deficiency of several nutrients to toxicity of Na. Plant growth in sodic soils is usually influenced by the osmotic and specific-ion effects and ionic imbalance leading to deficiency and or toxicity of some nutrients. In sodic soils, concentrations of Na often exceed those of most macronutrients by one or two orders of magnitude, and by even more in the case of micronutrients. Thus, sodic soil solutions may have depressed nutrient-ion activities and extreme ratios of Na/Ca, Na/K, Na/Mg. As a result, the salt- and Na-stressed plants become susceptible to high osmotic stress, specific ion toxicity and nutritional disorders. A collective effect of such stresses and disorders may reduce crop yield and quality (Grattan and Grieve, 1992). This depends upon the ambient sodicity concentrations, composition of the soil solution and exchange complex, soil pH and redox potential, the particular nutrient in question, salinity or sodicity resistance capability and nutrient requirement of the plant species grown, and several environmental factors. In addition, poor physical properties of sodic soils, which directly limit crop growth through poor seedling emergence and root growth, also exhibit indirect effects on plant nutrition by restricting water and nutrient uptake and gaseous exchange. Because sodic soils are usually hard, particularly in the subsoil, restricted root proliferation in such soils reduces water and nutrient supply (Qadir and Schubert, 2002).

Sodium and carbon (C) sequestration

Sodic soils have lost a large fraction of their original C pool. The magnitude of the loss may range between 10 and 30 Mg C ha⁻¹, depending on the antecedent pool and the severity of degradation. It is expected that the significance of C dynamics, as influenced by Na-related soil degradation, is expected to increase in future, as the extent of sodification is projected to expand considerably, especially in dryland areas (NLWRA, 2001).

Sodic soils compound soil organic carbon (SOC) loss by enhancing soil structure degradation and aggregate dispersion that on one hand increase SOC mineralization, yet on the other, restrict access to the substrate for mineralization by increased bulk density. Cycles of wetting and drying in saline-sodic cultivated soils play an important role in soil organic matter (SOM) decomposition. During wetting, aggregate dispersion enhances SOM decomposition, while drying leads to flocculation of aggregates and protection of SOM (Wong et al., 2010). In general, SOM-derived C stocks and fluxes in Na-affected soils are directly related to decreased plant inputs due to low biomass production and, hence, limited accumulation of soil organic matter that in turn affects soil C and nutrient cycling.

Sodic soils commonly occur in arid and semi-arid regions where they generally contain large pools of primary (lithogenic) and secondary (pedogenic) inorganic carbonates. Dissolution of the carbonates in the root zone could result from the accumulation of high $p\text{CO}_2$ (root respiration and decomposition of organic matter) or by acidic root exudates. The resulting HCO_3^- (bicarbonate) can then be leached, especially under irrigation management, down the soil profile and its subsequent precipitation is a possible pathway for C sequestration in an inorganic form. It is estimated that C sequestration through this mechanism ranges between 0.25 and 1.0 Mg C ha⁻¹ year⁻¹. Conversely, the presence of carbonates (CaCO_3) may limit SOM decomposition by bridging Ca ions to SOM particles, thus protecting SOM from microbial degradation (Golchin et al., 1994, in Wong et al., 2010). Yet, the subsequent turnover of the decomposition products under such circumstances is expected to be slower than the initial decomposition, thus leading to larger C concentrations and a longer retention time (Baldock and Nelson, 2000, in Wong et al., 2010). It has been concluded that a comprehensive understanding of the role of inorganic C in SOC dynamics, especially in sodic soils, is yet to be reached (Wong et al., 2010).

Information about the impact of the amelioration of sodic soils on C dynamics and stocks is meager and inconclusive. Moreover, it has been argued that the accumulation of organic matter in sodic soils might be difficult due to the high solubility of Na-organic linkages that are susceptible to removal by runoff or percolating water. Yet, revegetation of scalded lands with pasture has successfully increased SOM to the level of that of a native soil within 10 years (Wong et al., 2010). Use of leguminous trees has also been shown to increase SOM in Na-affected soils (Mishra and Sharma, 2003 in Wong et al., 2010). In addition, non-organic amendments such as gypsum have recently been found to be effective in alleviating sodicity stress, and increasing SOM pools (18% to 35%) and their stability in the Trans Indo-Gangetic Plains of India (Basak et al., 2021).

Finally, following the continued increase in sodicity related degradation of agricultural soils and the subsequent depletion in SOM, Wong et al. (2010) have proposed the following two key issues that are central to C dynamics and stock in soils:

1. The role of SOC dynamics in sodic soils for the assessment of C turnover.
2. Evaluation of the role of rehabilitation of sodic soils in the C cycle and its accumulation.

Concluding comments

The alkali metals group comprises six monovalent cations including K and Na that play a central role in agricultural soils. The importance of K arises from its being an important nutrient for plants. The potassium ion in the soil solution is the most available form for plants, yet just 1 to 2% of soil K is in this pool. Over 90% of soil K is within the crystal structure of soil minerals and in the fixed (non-exchangeable) pool found in the mica group of secondary minerals. Albeit defined as unavailable to plants, these two pools affect long term soil K fertility serving as large pools of K that replenish its depleted labile pools. Determination of its availability for plants is, therefore, central for economic K fertilization, supplemented with both soil tests and plant analyses for

actual fertilizer recommendations. Sodium is, in general, the dominant alkali cation in soils; its accumulation in soils often results in degradation of soil structure and associated physicochemical, physical and hydraulic properties. Productivity in Na-affected (sodic) soils is limited, also by crop tolerance to Na per se and plant nutrition in Na-affected soils. Sodicty related degradation of soil structure and associated properties subsequently leads to soil organic C depletion. Conversely, the rehabilitation of sodic soils may positively affect the C cycle and its accumulation in soils.

Abstract

The alkaline earth metals are Group 2 on the Periodic Table of the elements and are abundant in the Earth's crust and soils. They have +2 charge, minimal oxidation–reduction reactions, and moderate to high solubility in soils. Alkaline earth metals are abundant across the aluminosilicate, carbonate, and sulfate minerals. Strontium and barium are present in calcium-bearing minerals due to isomorphic substitution. Radium is predominately sourced from uranium-bearing rocks and minerals. The abundance and biogeochemical cycling of alkaline earth metals in soils is controlled by climate, parent material, and time as they control chemical weathering, precipitation reactions, type of rocks and minerals present, and leaching.

Key points

- Alkaline earth metals are Group 2 elements with +2 charge and minimal oxidation–reduction reactions and moderate to high solubility.
- Alkaline earth metals are released to soils by mineral dissolution and their speciation in soils depends on precipitation and adsorption reactions.
- Magnesium (Mg) and calcium (Ca) are essential for plants and animals while Be (beryllium), Sr (strontium), Ba (barium), and Ra (radium) do not serve essential functions and may be toxic at elevated concentrations.
- Magnesium and Ca can be added to soils through fertilizers to address deficiencies that reduce plant growth.
- Ratios of alkaline earth metals and their stable isotopes can be used as environmental tracers.

Introduction to alkaline earth metals

The alkaline earth metals comprise six metals in Group 2 (previously CAS group IIA) in the Periodic Table of the elements. Atomic symbols and atomic numbers for the alkaline earth metals are beryllium (Be) 4, magnesium (Mg) 12, calcium (Ca) 20, strontium (Sr) 38, barium (Ba) 56, and radium (Ra) 88. Since alkaline earth metals are lithophilic (rock-loving) elements and not siderophiles (iron (Fe)-loving), they are widely abundant in the Earth's crust and the resultant soils (White, 2020). Calcium and Mg are the fifth and eighth most abundant elements in the Earth's crust. Strontium and Ba are the 14th and 15th most abundant elements and are more abundant in the Earth's crust than other elements of similar atomic masses. The overall abundance of Mg, Ca, Sr, and Ba on Earth is due to their formation from nucleosynthesis through exploding massive stars and low mass stars (White, 2020). Conversely, Be and Ra are the 48th and 85th most abundant elements and are less abundant than other elements with similar atomic masses. Radium is rare due to its radioactive decay, with the longest living radioisotope being ^{226}Ra which has a half-life of only 1600 years and is produced from Uranium decay. Beryllium is also comparatively rarer than other light elements and is formed from early galaxy cosmic ray fission to form ^9Be or cosmic ray spallation on Earth to form ^{10}Be .

The alkaline earth metals have similar chemical and physical properties, largely due to their empty s-orbital, giving rise to +2 charge and minimal oxidation–reduction reactions at temperatures and pressures in terrestrial environments on Earth. Standard atomic weights increase with atomic number: Be 9.012182 g mol⁻¹, Mg 24.3050 g mol⁻¹, Ca 40.078 g mol⁻¹, Sr 87.62 g mol⁻¹, Ba 137.327 g mol⁻¹, and Ra 226 g mol⁻¹. Densities for the alkaline earth metals decrease from 1.85 g cm⁻³ for Be to 1.54 g cm⁻³ for Ca but increase from 2.64 g cm⁻³ for Sr to 5.5 g cm⁻³ for Ra. Ionic radius increases from 59 pm for Be⁺² to 253 pm for Ba⁺². Because of

this increase in atomic size with similar +2 charge, electronegativity decreases from 1.57 for Be to 0.9 for Ba and Ra on the revised electronegativity Pauling scale. Once hydrated, the Debye–Huckel effective radii range from ~500 pm for Sr^{+2} and Ba^{+2} to 800 pm for Mg^{+2} and Be^{+2} due to their hydration spheres (Garrels and Christ, 1965).

Speciation, dissolution, and precipitation in solution

The alkaline earth metals are characterized by their moderate to high solubility, insensitivity to fluctuations in oxidation–reduction conditions, and limited speciation under the typical pH range of soils. Fig. 1 shows the alkaline earth metals are predominantly at a + 2 charge and do not undergo oxidation or reduction reactions (Takeno, 2005). Of the alkaline earth metals, Mg, Ca, Sr, and Ba typically exist as dissolved ions (Mg^{+2} , Ca^{+2} , Sr^{+2} , Ba^{+2} , Ra^{+2}) in aqueous solution between pH 3 and 8 (Fig. 1). Only Be shows complex speciation and precipitation in the typical pH range of soils. Their large ionic radius and + 2 charge leads to a low charge density that forms weak hydration spheres which do not undergo hydrolysis but allows for ion pairing and complexation (Essington, 2015).

Chemical weathering of primary rocks and minerals is one of the dominant controls on the total abundance, plant availability, and mobility of alkaline earth metals in soils. Chemical weathering and release of alkaline earth metals depends on acid–base reactions, as alkaline earth metals do not undergo oxidation or reduction. As illustrated by Eq. (1), the dissolution of alkaline earth metals from aluminosilicates, in this case Ca and Mg from augite, is driven by the presence of acid. Acidity can be supplied from inorganic sources such as the dissociation of carbonic acid to bicarbonate, but can also be sourced from biotic sources including living organisms (bacteria, fungi, roots) and decomposed organic matter. Aluminosilicate dissolution in soils is considered irreversible to the original mineral due to thermodynamic constraints but, Al (aluminium) and Si (silicon) released can form a new aluminosilicate, such as kaolinite, through incongruent weathering (White, 2020).

Dissolution and precipitation of alkaline earth metals from carbonates is another acid driven reaction with a key difference from aluminosilicate dissolution that the reaction is reversible. Under moist, temperate soil conditions carbonates undergo dissolution while under dry, arid soil conditions carbonates precipitate. For example, Eq. (2) illustrates dolomite containing both Ca and Mg

Fig. 1 Speciation of Be, Mg, Ca, Sr, Ba, and Ra under pH range typical for natural waters and soils modeled using Visual MINTEQ at 10 nM 25 °C and 101 kPa.

undergoing dissolution when water and acidity (here carbon dioxide dissolving as carbonic acid) is present. However, the reaction can occur in reverse with precipitation of dolomite under increasing alkalinity in Eq. (2).

The precipitation of alkaline earth metals depends on anions present in solution. While carbonate precipitation is one of the most important at the global scale due to the rising abundance of CO_2 in the atmosphere, other essential anionic compounds and elements should also be considered, particularly: PO_4^{2-} (phosphate), SO_4^{2-} (sulfate), Cl^- (chloride), and F^- (fluoride). The formation of phosphate minerals with alkaline earth metals can be of great importance, as the family of compounds are highly insoluble with solubility constants (K_{sp}) of 1×10^{-24} or smaller. Sulfate compounds, such as gypsum and anhydrite, can also be important in dry environments. Sulfate compounds exhibit some solubility with a K_{sp} of 3.14×10^{-5} (Lide, 2005) and will precipitate if sulfate concentrations are elevated.

Sources to soils: Rocks and minerals

Alkaline earth metals are predominantly sourced to soils from rocks and minerals, particularly as aluminosilicates, carbonate, and sulfate minerals (Table 1). In particular, Mg and Ca are abundant across the five aluminosilicate mineral groups: (1) single tetrahedron nesosilicates (e.g. olivine, forsterite, garnet minerals), (2) double tetrahedron sorosilicates (e.g. epidote), (3) single and double chained inosilicates (e.g. diopside, rhodonite, wollastonite, hornblende), (4) sheet phyllosilicates (e.g. chlorite, talc), and (5) framework tetrahedron tectosilicates (e.g. anorthite). Minerals with the highest concentrations of Ca and Mg are carbonate minerals, specifically calcite. Other high Ca bearing minerals include dolomite and gypsum. Strontium and Ba are also present in Mg- and Ca-bearing aluminosilicate minerals due to isomorphic substitution. There is typically more substitution of Sr and Ba for Ca than for Mg, due to the closer similarity in radii and charge density. Strontium and Ba can be found in high concentrations in sulfate and carbonate minerals, such as celestite (SrSO_4), strontianite (SrCO_3), barite (BaSO_4) and witherite (BaCO_3). Beryllium can be found in Ca- and Mg-bearing aluminosilicate minerals at trace concentrations but is predominately sourced to soils from bertrandite, beryl, and phenakite minerals. Radium exists at trace concentrations in aluminosilicate minerals and is predominately sourced to soils from U-bearing minerals, such as uraninite.

The abundance of alkaline earth metal varies within igneous, metamorphic, and sedimentary rocks due to their geologic provenance (Table 2). Aluminium- and Si-rich felsic igneous rocks (such as granites) and Fe- and Mg-rich igneous rocks (like basalt) can have low to high abundance of alkaline earth metals. Felsic granites and rhyolite igneous rocks can have Ca- and Mg-bearing minerals that include feldspars such as anorthite, amphiboles such as hornblende, and potential inclusion of rhodonite and epidote. Similarly, mafic basalts and gabbro igneous rocks can have Ca- and Mg-bearing minerals such as olivine, forsterite, and augite. Igneous rocks that are dominated by Al, Si, and Na (sodium) bearing minerals can have relatively low amounts of alkaline earth metals while igneous rocks with high proportions of Fe and Mg can have low amounts of Ca and Sr. Sedimentary and metamorphic rocks generally have moderate to high abundance of alkaline earth metals depending on their source material, diagenesis, and the depositional environment they formed in. Most sedimentary rocks that formed in shallow marine environments have a high abundant alkaline earth metals due to biological detritus (e.g. shells of marine invertebrates). Sedimentary rocks formed from clastic sediments (e.g. sand, gravel, clays) can also include Ca- and Mg-bearing minerals in weathering resistant aluminosilicates such as feldspars. Metamorphic rocks that undergo hydrothermal alterations and high temperature and pressure alterations can have mineral assemblages with low to high alkaline earth metals. The abundance of Ra is controlled by the distribution of

U, which is an incompatible and highly soluble element. Thus, U and Ra are typically associated with coarse-grained granites (e.g. pegmatites) or hydrothermally altered rocks but can also occur in limestone, coarse sedimentary deposits, and faulted volcanic deposits.

Sources to soils: Atmospheric deposition

Alkaline earth metals can be supplied to soils by atmospheric deposition of particulates (e.g. dust), precipitation (rain, snow, fog), and interactions with plants, animals, and humans. The total abundance and composition of alkaline earth metals in atmospheric deposition depends on the source. For example, precipitation in remote areas across the world had Ca and Mg concentrations ranging from <0.1 to 68 $\mu\text{eq L}^{-1}$ and <0.1 to 321 $\mu\text{eq L}^{-1}$, respectively (Galloway et al., 1982). Close proximity to the ocean increases the marine influence and sea spray results in alkaline earth metal enrichment of soils. Volcanic eruptions can generate large deposition events locally during eruptions and be carried by atmospheric winds globally. Further, wind can carry dust and enrich other areas locally and across continents. A key example is the transport of Ca and Mg from the Saharan desert by wind to South America, which serves as an important source to the Ca and Mg poor soils of the Amazonian rainforests (Reichholf, 1986; Boy and Wilcke, 2008).

Plants, animals, and humans can also act as sources of alkaline earth metals to soils. Plants directly affect alkaline earth metals through uptake and cycling back to the soil surface. Plants also can release soluble metals from their leaves by precipitation, known as throughfall and stemflow. In addition, natural and human-caused fires can generate ash and dust that can carry alkaline earth metals to soils. Animals can release alkaline earth metals in their wastes, generating localized hot spots. Humans can also release alkaline earth metals intentionally as fertilizers (discussed later) or unintentionally as pollution from smelting, metallurgy, industrial processing, manufacturing, cement production, construction/demolition, and combustion of fuels (Kabata-Pendias and Mukherjee, 2007). As a prime example, metropolitan areas and industrial areas can have elevated Ca and Mg concentrations, with values ranging from 17 to 1570 $\mu\text{g L}^{-1}$ and 2 to 68 $\mu\text{eq L}^{-1}$, respectively, near the urban center of Chengdu, China and others globally (Wang and Han, 2011).

Partitioning and measurement of alkaline earth metals in soils

Alkaline earth metals are released in soils from primary minerals through chemical and physical weathering. Under physical weathering, alkaline earth metals can be released into soils as small immobile particles or lost from rock outcrops as sediments during mass wasting events. Chemical weathering, however, is one of the most important pathways for the release of alkaline earth metals from primary minerals. Alkaline earth metals are released as dissolved ions that can move with soil water in solution or become temporarily immobile through interaction with solid phase materials. Under dry, arid conditions, alkaline earth metals can precipitate as carbonate minerals, sulfate minerals, or as a salt minerals such as chloride, fluoride, or nitrate. Under moist conditions, alkaline earth metals can adsorb onto mineral surfaces, particularly those with a large surface area, and high charge clay minerals. Adsorption to Al, Fe, and Mn (manganese) oxides is also possible due to their pH-dependent charge, which is negative under moderately acidic to basic conditions. Lastly, alkaline earth metals can adsorb or chelate to solid or dissolved organic matter. Organic matter complexation depends on the functional groups present, molecular size and configuration, and pH-dependent charge. For example, chelation to citric acid can increase overall solubility of Ca and increase rates of Ca weathering into solution while oxalic acid can lead to precipitation of solid Ca-oxalate crystals (Sagoe et al., 1998). Adsorption onto insoluble organic matter can temporarily immobilize and retain alkaline earth metals for later uptake by plants.

The dissolved transport of alkaline earth metals through a soil profile depends on the partitioning coefficient, Kd, which is the ratio of metal adsorbed to soil particles divided by the concentration in the solution phase. The Kd value is an empirical measurement that describes the affinity of a dissolved ion to either adsorb to soil material surfaces or remain in solution and is unique to each soil. The Kd values for alkaline earth metals, as well as other metals, vary with the concentration of metals present in the system. To study the partitioning of metals, typically a single temperature is considered and the changes in Kd with

concentration are described by adsorption isotherms (Essington, 2015). There are several fundamental equations that can describe the slope and shape of adsorption isotherms for the alkaline earth metals for each soil. The samples and slopes rely on the solution pH, types of surfaces present, clay content, organic matter abundance, and temperatures of solutions. Using the K_d and adsorption isotherms, one- and two-dimensional transport rates for alkaline earth metals can be modeled. Alternatively, the production and downward transport of alkaline earth metals can also be modeled with a process-based approach, using thermodynamic and kinetic data for rates of mineral surface weathering, complexation with inorganic surfaces, complexation with organic surfaces, and chelation with ligands. This approach is more robust for application across spatial areas and time scales, but has significant drawbacks such as the demand for boundary conditions, initial conditions, and coefficients for the large number of potential chemical species and interactions.

To quantify alkaline earth metals in the environment, there are several sets of operationally-defined extractions used to estimate the fraction of each alkaline earth metal as a different chemical species. Typical schemes involve one or more of the following: a plant available, exchangeable, or bioavailable fraction, an organic matter bound fraction, a carbonate fraction, a secondary oxide fraction, and a residual fraction. Each fraction is defined with an explicit goal. Plant available, exchangeable, and bioavailable fractions are alkaline earth metals that are readily soluble for uptake by plants and animals. Typical extractions procedures utilize a salt (e.g. NH_4Cl , NH_4 -acetate see Rao et al., 2008) that can exchange for nutrients on cation exchange sites. This is a simple and rudimentary examination of the nutrients most available for plant uptake, but does not necessarily include other fractions that can be taken up or made accessible from rhizosphere processes: acidification, chelate secretion, and microbial symbionts. Measuring exchangeable Ca and Mg is a basic measure needed in agroecosystems. Calcium and Mg saturation of exchange sites contributes to the base cation saturation (which also includes Na and K) of a soil. The base cation saturation is an important measure for the availability of essential plant nutrients, but also a measure of soil acidification and susceptibility to Al toxicity for plants.

The organic matter bound fraction represents alkaline earth metals that may be available for plant uptake or potentially released during further decomposition of the organic matter. Typical extractions utilize a concentrated hydrogen peroxide or other compound to oxidize organic matter to CO_2 (Rao et al., 2008). The carbonate fraction is an estimate of alkaline earth metals precipitated as carbonate phases that may become dissolved under acidification by plant roots or increased amounts of precipitation. The carbonate fraction is measured using a weak acid extraction, specifically acetic acid, to acidify and dissolve carbonates but not dissolve silicate minerals (Rao et al., 2008). The secondary oxide fraction of alkaline earth metals examines adsorption to oxidation–reduction sensitive Fe and Mn surfaces, which can be important in highly weathered soils or soils that undergo periodic flooding. Oxides can be dissolved using reductants such as hydroxylamine, dithionite, or oxalate (Rao et al., 2008). The residual alkaline earth metals represent the remaining concentrations, typically within aluminosilicate minerals. However, alkaline earth metals within silicates such as feldspars or augite are not readily accessible to plants during a single growing season and thus can overestimate the potential uptake by plants. Total alkaline earth metal concentrations can be measured using X-ray fluorescence (Karathanasis and Hajek, 1996) or total digestion by HF-HNO_3 (hydrofluoric and nitric acids) at high temperatures and elevated pressures to dissolve the silicates (See Hossner, 1996). For all the fractions assessed through extractions and digestions, alkaline earth metals can be measured using several analytical instruments, such as the Inductively Coupled Plasma-Optical Emission Spectrometer (ICP-OES), Inductively Coupled Plasma-Mass Spectrometer (ICP-MS) or Atomic Absorption Spectrometer (AAS). Due to the moderate to high solubility of Ca and Mg, home colorimetric tests can be effective qualitative estimates. However, commercial and government laboratories can provide more specific, precise, and accurate measurements.

Climate, parent material, and time control on alkaline earth metals in soils

Soils are the integrated form of many physical, chemical, biological, and anthropogenic actions, but three dominant soil factors are considered to control alkaline earth metals in soils: climate parent material, and time. Climate can control the availability of water, which can drive or limit mineral dissolution and transport of alkaline earth metals from soils (Fig. 2). Under dry climates (aridic, xeric, parts of ustic) where evapotranspiration exceeds precipitation, alkaline earth metals can accumulate as carbonates, largely due to dust inputs and mineral dissolution exceeding leaching losses. For example, dry, aridic conditions of North Africa, Australia, western South America, western North America, and western Asia can lead to soils rich in alkaline earth metals due to limited precipitation and the formation of carbonate subsurface horizons. These dry soils in the US Soil taxonomic system include Aridisols (specifically gypsisols, calcids) and Mollicsols. Under the World Reference Base International soils classification system this includes Calcisols, Gypsisols, Kastanozems, and Chernozems. Excessive alkaline earth metals in soils can drive increases in soil, which lead to immobilization of other essential elements such as P. Under moist climates (parts of ustic, udic) where evapotranspiration does not exceed precipitation, alkaline earth metals are lost from the soil profile because atmospheric inputs and mineral dissolution are exceeded by leaching (Fig. 2). The loss of alkaline earth metals in soils can lead to acidic soil conditions which may cause excessive Al in soils. This is common in tropical and temperate areas of North America, northern Europe, northern Asia, and South America, particularly if intensive weathering occurs without carbonate-bearing parent material.

Parent material can control the abundance of alkaline earth metals present when soil formation begins. Carbonate-rich bedrocks can be found across North America, Africa, Europe, Asia, Australia, and in Brazil. They are typically sedimentary rocks formed in shallow ocean environments and their derivative soils are often rich in alkaline earth metals, particularly Ca. Conversely, soils derived from igneous rocks with high Al and Si content or high Fe and Mg content can have low availability of Ca due to the mineral assemblage present. Soils derived from sedimentary rocks from shallow marine environments typically have high Ca and Mg

Fig. 2 Conceptual model illustrating soil biogeochemistry of alkaline earth metals across dry ecosystems (desert, drylands), human-altered grassland ecosystems, and forested ecosystems. Arrows are approximations of size of the fluxes; moist soils with trees have greater aboveground cycling and downward leaching rates of alkaline earth metals while dry soils have limited plant-soil cycling and downward leaching rates of alkaline earth metals.

concentrations. Soils derived from metamorphic rocks can have low Ca content, for example soil derived from serpentine, or have low Mg content in soil derived from marble. Other soils with hydrothermally altered metamorphic rocks dominated by chlorite and talc can also affect plant growth due to their low Ca and high Mg concentrations.

Young soils (Entisols, Inceptisols, Mollisols, Alfisols) typically have higher alkaline earth metal contents than older soils (Ultisols, Oxisols). Younger soils still retain many primary minerals that are Ca and Mg bearing while extensive mineral dissolution through time will leave behind only secondary and recalcitrant Al, Si, and Fe bearing minerals. Older soils typically retain alkaline earth metals in their surface soils from biological uplift by vegetation, which is the retention of nutrient or nutrient-like elements through biogeochemical cycling from surface soils to roots to aboveground vegetation. Most soils contain adequate Ca for most plants and only highly leached, low-CEC, acidic soils are likely to cause Ca deficiency in plants. Old soils may be deficient in Ca and Mg, such as Oxisols and Ultisols in tropical regions of South America and Africa, due to extensive chemical weathering and removal by deep leaching. Young sandy soils at higher latitudes under wet, temperate conditions and extremely sandy soils can also lead to Ca deficiency in plants due to limited retention of Ca released during chemical weathering.

Plant requirements, uptake, and deficiencies for Ca and Mg

Of the alkaline earth metals, only Ca and Mg are known to serve as essential nutrients for plants and animals. Other alkaline earth metals, such as Sr and Ba, can substitute for Ca with limited effects on plant health unless elevated to concentrations that substantially shift the Sr/Ca or Ba/Ca ratio (e.g. Myrvang et al., 2016; Burger and Lichtscheidl, 2019; Kabata-Pendias and Mukherjee, 2007). For plants, Ca is a constituent of the plant cell wall and is involved in maintaining the turgidity of plants. Moreover, Ca is an essential aspect of chemical signaling; it is required for cell elongation, cell division, and enzyme activation, particularly those that are membrane-bound. Calcium also serves an important role in the synthesis of cell wall sugars (De Freitas et al., 2016). Magnesium is also an essential element for plants, with its paramount role as the central metal ion of chlorophyll *a* and *b* molecules in chloroplasts in plant leaves. Because of its ionic size and electronegativity, Mg cannot be substituted making it vital for plant health. Limitations in total abundance or an insufficiently bioavailable form of Mg reduces the ability for a plant to obtain enough Mg to synthesize chlorophyll for photosynthesis. Magnesium is also important for starch production during photosynthesis and serves many roles in the enzymes of plants.

Plants predominately obtain Ca and Mg from soils by mass flow with water. However, alkaline earth metals can also be taken up by diffusion, depending on soil solution chemistry and rate of transpiration of the plant. Uptake by the roots can occur through passive and active transport mechanisms. Passive uptake occurs by absorption from higher concentrations in the soil into the root tissues via apoplastic pathways moving between free spaces between cell walls. This is driven by electrochemical potential gradients and requires higher concentrations in the soil solution. Active uptake requires absorption via carrier molecules, such as organic ligands, against electrochemical gradients into cell walls.

Calcium deficiency causes a reduction in growth of meristematic tissues, where the affected tissue becomes soft due to dissolution of the cell walls. Calcium deficiency rarely occurs to the extent of having a negative impact on staple field crops such as maize (*Zea mays*), soybean (*Glycine max*), rice (*Oryza sativa*), and wheat (*Triticum aestivum*), but is more prevalent in fruit crops such as apples, watermelons, tomatoes, and bell peppers. Calcium deficiencies in fruits can be seen as water-soaked tissues from plasma membrane breakdown and dark brown lesions on the fruit surface. In fruits like apples, bitter pit occurs, where the flesh of the fruit under goes cell dehydration and death resulting in dark lesions on the fruit surface (Van der Boon, 1980). In fruits like tomatoes and watermelons, Ca deficiency leads to blossom-end rot, which is the decay of the fruit at the flowering end (De Freitas et al., 2016). For leafy vegetables, Ca deficiency is characterized by stunted growth, curling, and brown spots and necrosis in young leaves, leaf tips, and meristematic cells (De Freitas et al., 2016). Unlike other essential nutrients where deficiencies can be solved through nutrient transfer from other tissues to younger tissues, Ca can only be transferred within the xylem and cannot be transferred from older tissues to the fruit. Since Mg is closely associated with chlorophyll molecules in chloroplasts, Mg deficiency symptoms are chlorosis of the leaves, formation of pale white to yellow spots, and interveinal streaks. At later stages Mg deficiency results in necrosis in the leaves first affected by the deficiency.

Ca and Mg soil amendments

In agroecosystems, Ca is most commonly added to soils to address acidity issues, and secondarily to prevent or address deficiencies. Calcium and Mg are depleted from soils due to chemical weathering, leaching, and nutrient export from crops, while acid generating metals such as Al and Fe remain. Aluminium and Fe can hydrolyze water, creating acidity as water molecules are split to generate hydroxide ligands to neutralize their +3 charge in solution. Furthermore, roots, microbes, and organic matter generate organic acids and commercial fertilizers can also generate acidity (Zoca and Penn, 2017). Soils must be limed with Ca-rich materials to neutralize the acidity of the soil when the base cation saturation is <35%. Lime, a generalized mixture of Ca oxides and hydroxide phases, can be used to increase base cation saturation. There are many types of liming materials for soils, which include calcite (CaCO_3), dolomite ($\text{CaMg}(\text{CO}_3)_2$), slaked lime ($\text{Ca}(\text{OH})_2$), burnt lime (CaO), and wollastonite/slag (CaSiO_3). There are two important factors for considering liming materials. First, is the amount of Ca and acid neutralization of the material, which is typically measured as the calcium carbonate equivalent (CCE) or the acid-neutralizing ability of the material normalized to its weight in pure CaCO_3 . The other major consideration is the duration of the effect; compounds such as slaked lime and burnt lime will act faster than crystalline calcite, limestone, and wollastonite because of their higher solubility and surface area for reaction. Faster acting compounds will help immediately within the growing season while slower acting liming materials may take multiple growing seasons to fully react.

Another common Ca soil amendment is gypsum. Gypsum may be used to reduce acidity when used in combination with other liming agents, but results have been mixed when gypsum is used alone resulting in pH increases, pH decreases, or other small effects (see Zoca and Penn, 2017). More importantly, gypsum has been reported to add Ca^{+2} which reduces Al^{+3} activity and Al on CEC sites. Gypsum is more commonly used as a sulfur (S) source, which is important for several crops that have a large S demand such as brassicaceae (broccoli, cabbage, canola) and fabaceae (soybean, peas). Gypsum also has been used in soil reclamation, as it can help against soil dispersion in sodic soils, leading to greater water infiltration, soil aggregation, and soil porosity (Zoca and Penn, 2017).

Magnesium concentrations in natural ecosystem soils are typically at levels adequate for plant growth from primary mineral weathering, atmospheric deposition, and internal biological cycling. In agroecosystems, Mg concentrations are also typically adequate for crop growth either from primary mineral weathering, direct supplementation from liming, or indirectly through the addition of other fertilizers such as superphosphate. However, Mg can be added as readily soluble forms such as Epsom salt or as a slow released form from dolomite, magnesite, or serpentine. Dolomite is the most commonly used soil amendment because it adds both Ca and Mg and leads to a reduction in soil acidity.

An important aspect when considering the addition of Ca and Mg as soil amendments is to consider the relative abundance of other essential elements. Excess liming can raise the soil pH to neutral or even basic conditions, which will decrease the solubility and availability of other nutrients that are less soluble under higher pH conditions (Essington, 2015). As soil pH increases, micronutrients such as Fe, Mn, B (boron), Cu (copper), and Zn (zinc) become strongly adsorbed to exchange sites and become unavailable for plant uptake. Furthermore excess addition of Ca can limit the availability of P for plants through the precipitation of hydroxyapatite minerals. Thus, important considerations are necessary to avoid micronutrient deficiencies, precipitation of insoluble minerals such as hydroxyapatite, and to avoid pH extremes when adding lime and soil amendments.

Soil beryllium, strontium, barium, and radium toxicity to plants and animals

Of the alkaline earth metals Be, Sr, Ba, and Ra do not serve a known biological function and elevated concentrations in soil pose a potential threat to plants, animals, and humans (Kabata-Pendias and Mukherjee, 2007). However, Be, Sr, Ba, and Ra are present at low concentrations in unmanaged terrestrial ecosystems and agroecosystems with limited to no effect on plants. Quantifying the cause and effect between elevated concentrations of Be, Sr, and Ba is often difficult because of coinciding enrichments of other metals. Most information on the toxicity of these metals is derived from additions of soluble salts, hydroponic solutions, or unique geologic settings with high concentrations of an alkaline earth metal. For example, elevated concentrations of Be $>10 \text{ mg kg}^{-1}$ in

soil or 5 mg L^{-1} in soil solution could reduce crop yields between 30% and 88% (Romney et al., 1962; Kabata-Pendias and Mukherjee, 2007). Soils with elevated Be may reduce root and shoot growth, but the abundance of Ca and Mg, soil pH and clay content can prevent any negative effects of Be on plant growth (Shah et al., 2016; Tanveer and Wang, 2019). Similarly, elevated Sr and Ba concentrations can have potentially negative impacts on plant growth. Mixed effects have been observed with some studies reporting observations of decreased rates of shoot and root growth as well as decreased chlorophyll content, but also positive effects of growth, photosynthesis, and secondary metabolites (Burger and Lichtscheidl, 2019). Regarding Sr toxicity, radioactive Sr from nuclear waste and nuclear disasters are of primary importance. ^{85}Sr , ^{89}Sr , and ^{90}Sr undergo gamma and beta decay, releasing ionizing energy that can have radiotoxic effects resulting in damaged DNA in plants and animals (Burger and Lichtscheidl, 2019). Furthermore, radioactive Sr can generate highly reactive species of ion radicals that can produce reactive oxygen species that can damage cellular structures within cells. Barium has also been observed to have mixed effects of toxicity at elevated concentrations. Solutions containing Ba concentrations at $50 \mu\text{M}$ and less did not have a significant effect on bush bean growth, but solution concentrations of $500 \mu\text{M}$ negatively impacted root and shoot growth as well as leaves (Llugany et al., 2000). The toxicity of Sr and Ba are also controlled by the relative abundance of Ca and Mg and the adsorption or precipitation of Sr and Ba. Most studies have focused on absolute concentrations but identifying adequate ratios of alkaline earth metals in soils to prevent toxicity in important crops and tree species is of future importance to evaluate critically potential negative impacts from Be, Sr, and Ba. Due to its scarcity in typical terrestrial environments, Ra toxicity to plants is limited to areas with point source pollution, such as waste sites and mining areas. As a prime example, Abreu et al. (2014) found that increasing soil ^{226}Ra concentrations from former U mine soils did not generate physiological damage in lettuce (*Lactuca sativa* L.) and maize, and the application of Ca-bearing soil amendments decreased ^{226}Ra uptake.

Exposure to elevated or potentially hazardous concentrations of alkaline earth metals from soils is typically limited because of the small concentrations of Be, Ba, Sr and Ra relative to Ca and Mg. Soil with elevated alkaline earth metals from pollution or unique geologic formations can generate dust. One important exposure route of these metals is the soil to plant to animal or human transfer in areas that may be enriched naturally or from anthropogenic pollution. Agroecosystems in close proximity to current and former alkaline earth metal mines are of most interest. For example, Lu et al. (2019) studied Ba in rice paddy soils adjacent to a Ba mine and found mine water caused elevated Ba concentrations in the rice, but it represented a low risk only to human health if consumed. Urban gardens can contain elevated concentrations of Sr and Ba, which may be transferred to animals or humans that consume the plants. Toxicity of ^{90}Sr from soils to plants to humans from consuming vegetables, mushrooms, or dairy products also poses a threat in areas near nuclear accidents and nuclear waste sites, such as Chernobyl, Ukraine; Fukushima, Japan; and Indian Point, USA. Thus, the current body of literature supports the conclusion that human exposure to hazardous soil concentrations of alkaline earth metals or radioactive forms is very limited.

Alkaline earth metals as environmental tracers

The relative abundance of alkaline earth metals and their specific isotopic ratios have been used to understand natural and anthropogenically altered processes in soils. For example, the relative abundances of Ca, Mg, Sr, and Ba in rainwater, rocks and minerals, dust, plant materials, and soil horizons can be investigated using Ca/Sr, Mg/Sr, Ca/Ba, Mg/Ba, and Sr/Ba ratios to determine relative rates of inputs and internal cycling. As a prime example, the Sr/Ca ratio of seawater and unweathered Pahala Ash deposits were compared to soils to determine the relative importance of sea spray to supply alkaline earth metals to terrestrial ecosystems (Whipkey et al., 2000). Furthermore, the unique Sr/Ca ratios can be applied to forests to determine which minerals are the source of alkaline earth metals for the trees and rates of internal cycling. Furthermore, the ratios of stable isotopes of Sr, specifically the $^{87}\text{Sr}/^{86}\text{Sr}$, and stable isotopes of $^{44}\text{Ca}/^{40}\text{Ca}$ can be used to trace their source and movement in soils. The $^{87}\text{Sr}/^{86}\text{Sr}$ has been effectively used to investigate precipitation inputs, dust inputs, rock and mineral weathering, and human pollution to soils and terrestrial ecosystems. Similarly, native Ca or Ca-amended systems can be studied using the $^{44}\text{Ca}/^{40}\text{Ca}$ ratio to quantify the Ca source, uptake by plants and animals, and rates of biological cycling in terrestrial ecosystems and agroecosystems (e.g. van der Heijden et al., 2013). The application of these non-traditional stable isotope systems has tremendous possibilities to further the understanding of alkaline earth metals in soils, terrestrial ecosystems, and agroecosystems.

Conclusion

The alkaline earth metal group represents a set of elements with many chemical and physical similarities, but with distinct difference for plants and animals. The alkaline earth metals are an important group of metals that are widely abundant on Earth and in soils. They are not sensitive to fluctuations in reducing and oxidizing conditions and have a + 2 charge. Except for Be, alkaline earth metals are +2 ions in the typical pH range for soils. Calcium, Sr, Ba and Ra have similar atomic radii and can substitute for each other within minerals.

Calcium and Mg are the most important of the alkaline earth metals because of their role as major, essential elements within plants, animals, and humans. Calcium is needed by animals for chemical signaling and is required for cell elongation, cell division, and enzyme activation in plants. Magnesium is required as an enzyme cofactor in animals and is a critical component of chlorophyll

molecules in plants. Beryllium, Sr, Ba, and Ra do not serve a known role in the mineral nutrition of animals and plants and can be toxic at elevated concentrations under uncommon conditions.

Alkaline earth metals are sourced to soils predominately from the weathering of rocks and minerals, but can also come from atmospheric deposition and human inputs. The accumulation and retention of alkaline earth metals in soils is governed by their abundance in the parent material, rates of leaching and weathering controlled by climate, and duration for pedogenesis to occur. The study of alkaline earth metals has been primarily through total abundances and elemental ratios. More recently, stable isotopes have greatly advanced our understanding of their biogeochemical cycling at local, regional, and global scales.

Abstract

The chemical definition of transition metals is given, and terminology discussed. The origin, industrial uses and environmental fate of environmentally relevant metals are discussed briefly and references given.

Key points

- Transition metals are defined as metals of the d-block of the periodic table and generally have more than one oxidation state
- They exist in numerous oxidation states in soil and include cationic and anionic forms
- Some have been studied in depth and their fate in the environment is well documented
- They also include emerging pollutants for which more research is required

Introduction

Many of the elements in soil are metals, including transition metals. These elements have various sources, environmental fates and biological activity, making generalizations impossible. Of the 40 transition metals, only a small number are environmentally relevant in soils. Some essential feature of these elements and their dynamics in soil will be given and references for further information are indicated.

Definitions and terminology

The International Union of Pure and Applied Chemistry (IUPAC) define metals as elements which conduct electricity, have a metallic luster, are malleable and ductile, form cations, and have basic oxides. Transition metals are a large subgroup of metals. The

IUPAC has given two definitions. The older, more restrictive definition is an element whose atom has a partially filled d sub-orbital or shell, or which can give rise to cations with an incomplete d sub-orbital. However, since 2011 the preferred, broader definition is an element in groups 3 to 12 of the Mendeleev periodic table, namely all the d-block elements. In this definition, metals in group 12 (zinc (Zn), cadmium (Cd) and mercury (Hg)) with only two oxidation states (0 and +2) whose cations have complete d orbitals, are included, whereas they were formerly defined as post-transition metals. Lanthanides and actinides may be referred to as inner-transition metals.

Transition metals often have several environmentally relevant oxidation states, and may therefore be redox sensitive. An illustrative example of this is given by manganese (group 7) that exists in six oxidation states from +2 to +7. In contrast, metals of group 3 (scandium, yttrium and lutetium), although of little environmental importance, exist only as +3, in addition to the elemental form. At the other end of the transition series, group 12 (zinc, cadmium and mercury) exist as +2, with +1 in addition only for mercury. Another feature of transition elements is that due to d–d electronic transitions their salts are often colored. While not directly of importance in soil science, this property was important in elemental analysis of extracted metals by atomic spectroscopy. Many transition metals also form compounds that are paramagnetic, and this has important consequences for the use of nuclear magnetic resonance (NMR) spectroscopy in soil science. Transition metals also have richer complex, or coordination chemistry than s-block and p-block metals. This is important for their chemistry and dynamics in soils. The Pearson Hard–Soft Acid–Base theory may be useful to predict some aspects of the coordination theory of transition metals. This theory allows a qualitative prediction of the strength of association between Lewis acids (electron pair-acceptor) and Lewis base-donors; soft-soft and hard-hard interactions being favored over hard-soft. The smaller, high charge weakly polarizable cations to the left of the periodic table are hard, and thus associate with oxygen ligands. Heavier (second and third row) metal cations tend to be soft, and associate with hydrides and sulfur-containing ligands. However most of the environmentally relevant transition metals are borderline between hard and soft.

The terminology of transition metals may be confusing. The term was first coined by the chemist Charles Rugeley Bury in 1921. As stated above, the IUPAC definition of transition elements has varied over time, to exclude or include elements of groups 3 and 12 that are d-block elements, but do not have incomplete d orbitals in all oxidation states. However despite many criticisms, the term ‘heavy metal’ is still widely used (Duffus, 2002). This loosely defined term often encompasses metals and metalloids with density greater than 5 kg dm⁻³. The term implies contaminants with toxic properties. But elemental density has no relation with chemistry or biological properties. Some metals have no known biological role, while others may be micronutrients, required at small levels for example in catalysts, but can become toxic at excess levels. The terms trace element or metal make no assumptions about the biological role of the element, simply excluding major elements such as iron (Fe), aluminum (Al) and manganese (Mn). The terms ‘potentially toxic’ or ‘nutrient’ have biological meaning, but no chemical implications; transition element or metal has chemical meaning, but includes elements with a wide range of biological properties. Heavy metal, although used in toxicological literature and by legislative authorities in many countries, is neither well-defined nor informative, and should be avoided.

Sources and environmental fate

The sources of transition metals in the soil environment are variable. In most ecosystems, most of the metals present are of natural, geological origin. For example, iron and manganese are major components of soils; they are carrier phases for other metals, which influence their dynamics. In restricted geographic areas a metal may be present naturally with contents that are considered excessive. The best-known example is nickel (Ni) in soils developed on serpentine that may contain up to 100 times the world average Ni content (20 mg kg⁻¹). There are cases of deficiency in some metals in agricultural systems, particularly for copper (Cu), zinc, nickel and molybdenum (Mo). Soils may be contaminated by transition metals due to human activity, notably agricultural and industrial activity. Source of metal addition to soils may be atmospheric fallout from industry, and transport, and agricultural amendments, including phosphate fertilizers containing cadmium, manure and sludge containing copper and zinc. New technology leads to emerging pollutants, with different chemical and biological properties. The dynamics of these metals, including titanium, yttrium, zirconium, tantalum, tungsten, and zirconium are as yet poorly understood and documented (Souza et al., 2021).

In general native, or legacy, metals in soil, largely of geochemical origin, are not labile and contribute little to the bioavailable and mobile fractions of the metals in soil. More recently added metal, whatever the origin, but depending on the chemical form, tends to be more mobile, labile and bioavailable. Added metal salts are rapidly precipitated, adsorbed on soil minerals, and complexed with soil organic matter. In general, only a tiny proportion remains in solution, and this proportion is also influenced by the formation of soluble or colloidal complexes in solution. With time, recently added metals tend to become less labile, more fixed on the soil organo-mineral complex; a process known as attenuation.

The dynamics of transition metals in soil depend on soil redox conditions. There are both direct and indirect influences: most transition metals have redox chemistry and so their oxidation state, and thus mobility, reactions with soil minerals and biological properties, depend on the redox state. In addition, as for other elements in soil, the redox-sensitive solubility of carrier phases such as iron and manganese (oxy)hydroxides influences the immobilization or solubility of other metals.

When soils are contaminated by transition metals, there are various strategies to manage these soils and these have been treated in other chapters. Briefly, these include

- phytoextraction, where plants are used to extract metal thus decreasing the amount in soil, assuming that labile metal is removed which leaves progressively less bioavailable metal in the soil, therefore effectively cleaned-up to some extent

- use of non-food crops or non agricultural land use
- covering very contaminated soil with other soil and growing crops to stabilize the soil physically against erosion
- use of soil amendments to provide carrier phases to immobilize the contaminant, to change soil pH, or to improve the nutrient status of soil to compete with contaminant metal cations and thus reduce their uptake.

Examples of environmentally relevant metals in soil

Of the 40 transition metals, only a small number are environmentally relevant in soils. Essential information on these metals is considered below. Compendia of reviews of the chemistry and biological properties of metals in soils can be found in text books, notably *Kabata-Pendias and Mukhrjee (2007)* and *Coughtrey and Thorne (1983)*, although the latter focuses on elements whose radioactive isotopes may be found in the environment. Trace element deficiencies and their causes, with emphasis on soils of England, are reviewed by *Thornton and Alloway (1974)*, and recent advances in the understanding of micronutrients has been reviewed by *Singhal et al. (2022)*. References are given in subsections only if recent reviews are available for elements with relatively little published data.

Scandium. Group 3 (formerly IIIB)

Scandium (Sc) is in the first row and first group of the transition metals, atomic mass 44.96, present as Sc^{3+} , that can substitute for Al and Fe. It is present naturally in soils, often associated with biotite and igneous rocks and released by uranium processing and some industrial processes. There is little information on this element, and it has no known beneficial biological role.

Titanium. Group 4 (formerly IVB)

Titanium (Ti) is in the first row and second group of the transition metals, atomic mass 47.87, and often present in the tetravalent form in titanates and silicates. It is relatively abundant in the Earth's crust, $0.4\text{--}0.6\text{ mg kg}^{-1}$, and so is present naturally in soils, with a mean of about 0.3 mg kg^{-1} . Although it may be released into the environment from some industrial processes, notably paint production, it has been little studied. Its oxide is however an emerging contaminant as a nanoparticle. It has various industrial uses, including as a component of steel alloys, in catalysts, the textile industry.

Vanadium. Group 5 (formerly VB)

Vanadium (V) is in the first row and third group of the transition metals, atomic mass 50.9; it exists in various oxidation states, from -3 to $+5$, forming anions and cations. Its abundance in both the Earth's crust and soils is about 60 mg kg^{-1} , which makes it one of the most abundant elements. It is widely used in many industries, and anthropogenic activity thus creates a potential pollution risk. It appears to be an essential micronutrient, and small additions may promote plant growth, however it may become toxic in excess. Its complex redox chemistry makes the study of its dynamics complicated, and therefore rather little information is currently available (*Chen et al., 2021*).

Chromium. Group 6 (formerly VIB)

Chromium (Cr) is in the first row and fourth group of the transition metals, atomic mass 51.9; it exists in various oxidation states, the most common being $+3$ and $+6$, in addition to the elemental form, and occurs as both anions and cations. Background contents of Cr in soil vary, but an average may be about 50 mg kg^{-1} with larger contents at depth than in surface soils. Very large sources of Cr have been reported in serpentine soils, and there are numerous anthropogenic sources of Cr in the environment because of its industrial uses, notably in the tannery industry, steel production, electroplating and the chemical industry. Although there is no known beneficial role for Cr in plants, it is an essential micronutrient for animals, although toxic or dermo-irritant at larger concentrations. The speciation of chromium depends strongly on redox potential and pH. The $+3$ form is the most stable under most environmental conditions. This form is strongly sorbed on soil, and thus is very immobile, except in very acid soils, with correspondingly low bioavailability. It also interacts with organic and inorganic ligands to form complexes however this form is also much less toxic to living organisms than is the more oxidized form. The hexavalent form is considered to be among the most harmful of pollutants and is readily absorbed by inhalation, ingestion and absorption. The mechanism of its toxicity is largely due to its strong oxidizing capacity, thus forming reactive oxygen species. More information is reviewed by *Ertani et al. (2017)*.

Manganese. Group 7 (formerly VIIB)

Manganese is in the first row and fifth group of the transition metals, atomic mass 54.9, with variable oxidation states, from $+2$ to $+7$. Manganese is an abundant element in both the Earth's crust and in soils. The manganese contents of soils worldwide vary by more than 3 orders of magnitude from about 7 to over 9000 mg kg^{-1} , depending on geological origin and texture. Manganese (hydr)oxides, often amorphous, are important minerals in soil that are formed, solubilized and reformed under varying redox

conditions, contributing to the dynamics of many other elements. The most important oxidation states are +2, +4 and +7, with both cationic and anionic forms, and numerous organic and inorganic complexes in solution, including many with hydroxyl groups (e.g. MnOH^+ , $\text{Mn}_2(\text{OH})_2^{2+}$, Mn_2OH^+).

In addition to naturally occurring manganese, the numerous industrial uses of manganese including metallurgy, pigments, and transport, contribute to its addition to the environment. Manganese is an essential micronutrient contained in many enzymes for example. However while excess exposure can be toxic, there is no evidence of manganese toxicity from environmental sources. Most soil science research on manganese focuses on the dynamics of manganese oxides under fluctuating redox conditions and their roles as carrier phases (Berg et al., 2015; Li et al., 2021).

Iron. Group 8 (formerly VIII)

Iron is in the first row and sixth group of the transition metals, atomic mass 55.8, with variable oxidation states, from +2 to +6, predominantly +3. Iron is the most abundant metal in the lithosphere, accounting for about 4.5% of the Earth's crust and between, 0.1 and 10% of soil. It occurs as oxides and hydroxides, both amorphous and crystalline minerals, and forms coatings on clay minerals. Amorphous iron oxides may make an important contribution to soil specific surface area, particularly in tropical soils where the major clay mineral is kaolinite. It is an important carrier phase for other metals, and for organic matter and phosphate. It has a complex geochemistry that depends strongly on the Eh–pH system. Like manganese, the dynamics of iron minerals, especially under fluctuating redox and pH conditions, determine the dynamics of many other metals in soil. Transport and transformation of Fe minerals determine much of soil weathering and development. Iron is often a major contributor to soil color, with red or yellow colored minerals including hematite, goethite and magnetite.

Iron is an essential nutrient for plants and animals, being an important component of many organic compounds, including proteins. Iron toxicity exists, but the cause in humans is generally by poisoning, not environmental exposure. Iron deficiency in humans and other animals may be caused by both physiological disorders and inadequate dietary intake. In plants, iron deficiency (chlorosis) may occur in alkaline or calcareous soils, or soils with excess amounts of cations of similar size such as Mn, Ni or Co. Some plants have mechanisms to cope with iron deficiency, including the release of phytosiderophores and reduction of Fe^{3+} .

Cobalt. Group 9 (formerly VIII)

Cobalt is in the first row and seventh group of the transition metals, atomic mass 58.93, with oxidation states, of +2, +3 and +4, predominantly +2. Cobalt is present with similar contents in both the Earth's crust and soil, namely about 10 mg kg^{-1} . It is contained in various minerals often associated with sulfur (S), selenium (Se) and arsenic (As), and its geochemical cycle resembles those of Fe and Mn. Its major industrial use is in metallurgy, with smaller requirements for the pharmaceutical industry, fuel production, pigments and plastics. There is little evidence of soil contamination by Co, except near some metal processing plants, and so soil contents are usually determined by parent materials and soil-forming processes. Soil contents tend to be greatest in serpentine soils and soils in arid and semiarid regions, and lowest in colder climates. Cobalt is often associated with iron and manganese oxy-hydroxides, and thus is sensitive to redox conditions.

Cobalt is an essential nutrient for plants and animals. It is a component of vitamin B12 and can be deficient for grazing animals on many soils (Hu et al., 2021; Singhal et al., 2022). It is also essential for symbiotic nitrogen (N) fixation. Deficiency is generally addressed by nutrient supplements rather than soil amendments.

Nickel. Group 10 (formerly VIII)

Nickel is in the first row and eighth group of the transition metals, atomic mass 58.69, with oxidation states, of +1, +2, +3 and +4, predominantly +2, with little environmentally relevant redox chemistry. Nickel is present in similar amounts in both the Earth's crust and soil, namely about 20 mg kg^{-1} , but with a large range and up to 450 in serpentine soils. The major industrial use of Ni is in the steel industry, but it is also used in ceramics, food technology and catalysis. In soil, Ni is associated with Fe and Mn (hydr)oxides and organic matter.

Nickel is an essential element, but there is little evidence of deficiency. However it is potentially toxic at elevated concentrations; its mobility, particularly in sandy soils (Luo et al., 2017), and phytoavailability may be problematic when plants are grown on contaminated soils. Plants growing on serpentine soils have developed the ability to hyperaccumulate Ni and then to sequester it with chelating agents as a tolerance mechanism (Brady et al., 2005). Topsoil contamination has been reported near smelters, and after the use of contaminated sludges. In a few cases there is evidence of atmospheric deposition on soil after long distance transport of atmospheric Ni.

Copper. Group 11 (formerly IB)

Copper is in the first row and ninth group of the transition metals, atomic mass 63.54, with oxidation states, of +1 and +2, predominantly +2, with little environmentally relevant redox chemistry. Copper is present in similar abundance in both the Earth's crust and soil, namely about 20 mg kg^{-1} , but with a large range from 1 to over 100. Copper was one of the first metals known to man and has been used for millennia. Copper minerals are usually sulfides, oxides or more rarely carbonates. Industrial uses of

copper are numerous and include metallurgy, art, ammunition and telecommunications, and even in modern times, its earliest uses in jewelry and coinage remain. Another environmentally significant use of copper is in agriculture. It is a feed additive for livestock, and a common pesticide, particularly in vineyards and in organic agriculture.

Copper is associated with clay minerals, organic matter, carbonates and Fe and Mn oxyhydroxides. It has little environmentally relevant redox chemistry.

Copper is an essential nutrient and deficiency has been reported in many soils and agricultural uses. The treatment of deficiency tends to be foliar sprays for crops and feed amendments for livestock, rather than soil amendments. Copper contamination of soils has been the object of numerous studies. The sources are both industrial and agricultural, in particular for vineyard soils and soils subjected to sewage sludge amendments. The low mobility of Cu in soils means that although the bioavailability of Cu is quite poor, it remains present in soils for a long time. Since vines are deep-rooting and often suffer no ill-effects from surface applied Cu, even after years of accumulation (Ruyters et al., 2013). Problems of phytotoxicity occur after land-use changes. There is also much evidence of Cu-related deterioration of soil microbial activity.

Technetium. Group 7 (formerly VIIB)

Technetium (Tc) is in the second row and fifth group of the transition metals, below manganese, atomic mass 98.9, with oxidation states, of +4, +6 and +7, and it occurs mainly as the heptavalent oxyanion, TcO_4^- . All the isotopes of Tc are radioactive. Tiny amounts of Tc are found in uranium ore. The sources of Tc in the environment are from fallout and nuclear processing. All the research on this element has been in the field of radioecology and some of its properties and environmental fate have been discussed in the chapter on radionuclides in the environment.

Palladium. Group 10 (formerly VIII)

Palladium (Pd) is in the second row and eighth group of the transition metals, below nickel, atomic mass 106.42 with oxidation states of +1, +2, +3 and +4, but predominantly +2. Its abundance in the Earth's crust is about $10 \mu\text{g kg}^{-1}$, with similar, slightly larger amounts in soil. It is a noble metal and a member of the platinum group metals (PGM), namely iridium, osmium, palladium, platinum, rhodium and ruthenium, recently reviewed by (Savignan et al., 2021). These metals are exceptionally rare, are often found together and have similar chemical properties. All are increasingly used in new technology and are therefore potential emerging pollutants. In particular, their use in catalysts leads to contamination from automobile exhaust catalysts. Almost all the soil science research on palladium to date involves monitoring of soil content and analytical techniques. It is known to be toxic to humans when inhaled, but no data are available on the consequences of environmental contamination.

Silver. Group 11 (formerly IB)

Silver (Ag) is in the second row and ninth group of the transition metals, below copper, atomic mass 107.87 with oxidation states of +1, +2 and +3, but predominantly +1. It is a noble metal, known and appreciated by man in jewelry for millennia. It is scarce, and occurs in the Earth's crust at contents of about $70 \mu\text{g kg}^{-1}$, and in the range $0.06\text{--}0.4 \text{ mg kg}^{-1}$ in soils, with larger amounts in organic soils, up to 5 mg kg^{-1} . Jewelry remains one of the major uses of silver. Its use in photography and in X-ray films has decreased dramatically, while various industrial applications and medical uses remain. In soil, silver is associated with sulfides and organic matter. There are few data on silver mobility and bioavailability in soil, and these have been reviewed by (Wang et al., 2018). Silver nanoparticles may be an emerging pollutant, because of their antimicrobial properties that make them attractive in textiles, food, medical and pharmaceutical industries. However their toxicity would be related to their size rather than the chemical and biological properties of the element. Silver has no known biological role.

Cadmium. Group 12 (formerly IIB)

Cadmium is in the second row and tenth group of the transition metals, below zinc, atomic mass 112.41 with oxidation states of +2. Its abundance in soil is about 0.5 mg kg^{-1} , it has a similar chemistry to Zn, with a greater affinity for sulfide. It is often a byproduct of mining for Zn. It is widely used in batteries and in pigments. In soil it is associated with colloids, sulfides and organic matter. Its dynamics are strongly related to pH, partly due to its complex formation. It may precipitate at alkaline pH and under reducing conditions due to sulfide formation.

There are many anthropogenic sources of Cd in soils, the most important being atmospheric deposition and the use of phosphate fertilizers (Liu et al., 2019). Plant uptake may be reduced by soil liming, although other techniques such as land-use change, phytoremediation and inoculation with microorganisms have been tested. There is no known beneficial role for cadmium in plants or animals and it is one of the most toxic elements to man. The mechanisms of toxicity involve its binding with sulfur groups of proteins, and enhancing the production of reactive oxygen species. However one of the major sources of human intake of cadmium is from smoking tobacco.

Tantalum. Group 5 (formerly VB)

Tantalum (Ta) is in the third row and third group of the transition metals, below vanadium, atomic mass 180.09 with oxidation states of +3, +4 and +5, mainly +5. Its abundance in soil is about 1 mg kg^{-1} , about half that in the Earth's crust. Although there have been few studies of Ta, its increasing use in both surgery and electronic devices makes it a potentially emerging pollutant.

Tungsten. Group 6 (formerly VIB)

Tungsten (W) is in the third row and fourth group of the transition metals, below chromium, atomic mass 183.8 with oxidation states from +2 to +6, mainly +6. Its abundance in soil is about 1 mg kg^{-1} , similar to that in the Earth's crust. There have been few studies of W in the environment, although elevated soil contents have been observed around industrial plants, including ore processing plants. There is some evidence that W may have a biological role, and that it may compete with Mo in reductase reactions in plants. Its increasing use in metal alloys, in pigments and automobile exhaust catalysts make it a potentially emerging pollutant.

Osmium. Group 8 (formerly VIII)

Osmium (Os) is in the third row and sixth group of the transition metals, below iron, atomic mass 190.2 with oxidation states of +3, +4, +6 and +8, mainly +3. Its abundance in the Earth's crust is about $1 \text{ } \mu\text{g kg}^{-1}$. It is a member of the platinum metal group. It is increasingly used in electronic devices. Non-elemental forms are thought to be mobile and are known to be highly toxic.

Iridium. Group 9 (formerly VIII)

Iridium (Ir) is in the third row and seventh group of the transition metals, below cobalt, atomic mass 192.2 with oxidation states of +2, +3, +4 and +6, mainly +4. Its abundance in the Earth's crust is about $0.5 \text{ } \mu\text{g kg}^{-1}$. It is a member of the platinum metal group. It is increasingly used in specialist alloys and electronic devices. It appears to be mobile and bioavailable, although no biological roles or adverse effects are known.

Platinum. Group 10 (formerly VIII)

Platinum (Pt) is in the third row and eighth group of the transition metals, below nickel, atomic mass 195.07 with oxidation states of +2, +3, +4 and +5, mainly +4. Its abundance in the Earth's crust is variable, but low, in the range of $\mu\text{g kg}^{-1}$ and is associated with ores containing other PGM. It is a noble metal and gives its name to the platinum metal group. It is well known for its use in jewelry and is increasingly used in specialist alloys, catalysts and medical devices. Its major source in the environment appears to be from road traffic. It appears to have some mobility and bioavailability, but there is currently very little information on toxicity. The distribution, fate and possible toxicity of PGM have recently been reviewed (Savignan et al., 2021).

Gold. Group 11 (formerly IB)

Gold (Au) is in the third row and ninth group of the transition metals, below copper, atomic mass 196.97 with oxidation states of +1 and +3, mainly +1, in addition to the elemental state. Its abundance in the Earth's crust is about $3 \text{ } \mu\text{g kg}^{-1}$. It is a noble metal, and often found in the elemental state. It was one of the earliest metals known to man and is still well known for its use in jewelry. Although gold may be found as large, easily identified nodules, the more finely divided metal may be extracted using flocculation with mercury or cyanidation; both environmentally hazardous processes. Despite its chemical inertia and dominance of the elemental form, oxidized forms of gold have some mobility in the environment and bioavailability. There is some evidence of toxicity, but due to professional exposure rather than dietary intake for humans.

Mercury. Group 12 (formerly IIB)

Mercury (Hg) is in the third row and tenth group of the transition metals, below zinc, atomic mass 200.59 with oxidation states of +1, +2 and +3, mainly +2, in addition to the elemental state. Its abundance in the Earth's crust is in the range $20\text{--}60 \text{ } \mu\text{g kg}^{-1}$, with a similar content in soil. It is a liquid in the elemental state, and is probably best known for its use in thermometers. Its dispersal in the environment is facilitated by the volatilization of elemental Hg and to a lesser extent methylated forms. Its production and industrial use tends to decrease, largely because of its toxic properties. It is highly toxic to microbes, plants and animals. A considerable volume of literature exists on its toxic properties, particularly methylated species (Natasha et al., 2020).

Conclusions

Transition metals are a chemically and biologically heterogeneous group, and many of these elements have significant environmental impact. Research will continue on the dynamics and fate of traditional metal pollutants and micronutrients. However the most exciting aspect of transition metal research will focus on emerging pollutants released by innovative technology and the unravelling of the biological processes involving trace amounts of these metals as essential nutrients or toxic substances (Fig. 1).

Abstract

Soil nitrogen transformations underpin plant growth and are fundamental to healthy ecosystem functioning. Excess nitrogen applications, particularly in the form of high fertilizer inputs, adversely affect soil health and cause substantial nitrous oxide and ammonia emissions, contributing to climate change and atmospheric pollution. Understanding nitrogen transformations in soil is therefore an important first step to devising mitigation strategies. Dominant nitrogen pathways include mineralization of organic nitrogen into plant available forms (ammonium and nitrate), and subsequent nitrification and denitrification, which ultimately produce nitrous oxide and/or dinitrogen. A range of techniques is now available for quantifying soil nitrogen turnover and partitioning pathways, including the application of stable isotopes and micro-meteorological methods.

Glossary

Aminization The first stage of nitrogen mineralization, and the process by which complex proteins are broken down into smaller amino acids, amides and amines.

Ammonification The second stage of nitrogen mineralization, and the process by which organic forms of nitrogen, including amino acids, amides and amines, are converted into ammonia or ammonium.

Denitrification The reduction of nitrate and nitrite to gaseous forms of nitrogen, including nitrous oxide and nitrogen, occurring under anaerobic conditions.

Immobilization The uptake of nitrate and ammonium by the soil microbial community.

Nitrification The oxidation of ammonia to nitrite, occurring under aerobic conditions.

Nitrogen fixation The process by which atmospheric nitrogen is assimilated into organic compounds.

Mineralization The conversion of organic nitrogen into inorganic, plant available forms of nitrogen.

Key points

- Nitrogen is an essential element for plant growth and is often added in agricultural systems to maintain yields.
- Nitrogen applications are often in excess of crop demand driving substantial gaseous emissions and ultimately causing adverse environmental impacts.

- Soil nitrogen turnover is dominated by the processes of nitrification and denitrification, but other processes (for example codenitrification) may make important contributions under specific circumstances.
- A range of methodologies is now available for quantifying the scale of nitrogen losses and tracing soil nitrogen dynamics, and collectively creating new opportunities for improving nitrogen use efficiency and mitigating emissions.

Introduction

Nitrogen is an essential element for plant growth, and ultimately underpins food security. High rates of application of nitrogen fertilizer, often in excess of crop demands, alongside pollution, have substantially increased the transfer of nitrogen into soil systems, and the atmosphere. This has led to a range of adverse environmental impacts across a range of ecosystems. For example, substantial nitrous oxide (N_2O) emissions are an important contributor to climate change. Moreover, the impacts of climate change are likely to affect soil nitrogen transformation pathways, potentially leading to climate feedbacks. Balancing the need for nitrogen to maintain agricultural production, and concurrently mitigating gaseous emissions of N_2O and ammonia (NH_3) requires a thorough understanding of pathways, and the mechanisms which regulate them. Equally a similar understanding is also needed for many other ecosystems, from peatlands to tropical forests, to understand potential climate responses.

The need for nitrogen

Nitrogen plays a vital role in plant growth; a deficiency in nitrogen and plants cannot thrive, leading to low crop yields; but an excess of nitrogen can be toxic to plants and have detrimental effects on the environment. Nitrogen is a key component of plant proteins (as a constituent of amino acids, the building blocks of proteins) and chlorophyll (the most important pigment needed for photosynthesis), which significantly impacts plant productivity. Nitrogen is a naturally occurring gaseous element, accounting for approximately 78% of the Earth's atmosphere. However, plants are unable to utilize the element in this form (N_2). To be available to plants, nitrogen must be transformed through the nitrogen fixation process to the reduced forms of this element.

Nitrogen can be produced naturally through three main pathways:

- I) Lightning - A small amount of nitrogen is fixed when lightning provides the energy required for atmospheric nitrogen (N_2) to react with oxygen, producing nitrogen oxide (NO) and nitrogen dioxide (NO_2). These forms of nitrogen then enter the soil system through atmospheric deposition in rain or snow.
- II) Biological - Nitrogen fixation also occurs naturally in the soil, carried out by a specialized group of prokaryotes. These organisms utilize the enzyme nitrogenase to convert atmospheric nitrogen to NH_3 (NH_3). Another important process occurs when legumes are present. Legumes are able to form symbiotic relationships with nitrogen fixing bacteria called rhizobia. This symbiosis results in nodule formation on the plant root, within which the bacteria can convert atmospheric nitrogen into NH_3 which can be used by the plant.
- III) Organic matter decomposition - Dead organic matter on and/or in the soil profile is decomposed by a wide range of microorganisms, called decomposers. These organisms consume and break down the organic matter and the nitrogen that is subsequently released is converted to plant accessible inorganic forms.

However, even with natural nitrogen fixation, low nitrogen concentrations in soils still often limit plant growth. When this happens, plant accessible forms of nitrogen must be added manually to ensure successful plant growth. Artificial nitrogen fixation, through the Haber-Bosch process, is the main industrial method for the production of NH_3 . This is where atmospheric nitrogen can be combined with hydrogen (H^+) to make anhydrous NH_3 and other nitrogen fertilizer products which are manually added to the soil. The use of nitrogen fertilizer has risen from 11 million tonnes in 1961 to 137 million tonnes in 2013, supporting substantial increases in crop production to feed a growing, global population. However, despite the clear successes of modern agriculture, an estimated 50% of applied nitrogen fertilizer is lost to the environment in water run-off from fields, animal waste and gaseous emissions from soil-microbe metabolism. These trade-offs have diverse and far-reaching impacts on public health, the environment and the economy. For example, excess nitrogen in the water causes algae to grow faster than ecosystems can handle (eutrophication). Significant increases in algae harm water quality, food resources and habitats, and decrease the oxygen that fish and other aquatic life need to survive. Excessive application of synthetic fertilizers has also been shown to acidify soils, damaging soil health and reducing the productivity of soils. Surplus nitrogen in the soil can also be oxidized and lost to the atmosphere as N_2O , which is a long-lived greenhouse gas that contributes to global warming. It persists in the atmosphere for an average of 114 years and is 300 times more potent than carbon dioxide. Mitigating these adverse effects requires an understanding of the dominant processes of soil nitrogen turnover.

Soil nitrogen transformations

Nitrogen compounds in soils

Soil nitrogen has three dominant forms: organic nitrogen, ammonium (NH_4^+) and nitrate (NO_3^-), the latter of which are the only ones accessible to plants for growth, although other forms of nitrogen appear as intermediaries in transformation pathways (for example nitrite, NO_2^-), or else are released as gaseous end products (for example N_2O) (Table 1). Examples of organic nitrogen include the nitrogen present in plant material (for example proteins and DNA), and waste material (for example manure and urea).

Nitrogen transformations are key to making nitrogen available for plant growth and include mineralization (the conversion of organic nitrogen to inorganic forms), nitrification (the conversion of NH_4^+ to NO_2^- and NO_3^-), denitrification (the conversion of NO_3^- to N_2O and nitrogen gas) (Fig. 1). However, a range of additional, and frequently less well characterized pathways, can also make potentially significant contributions to nitrogen turnover under certain prevailing soil conditions. Examples of such processes include Anammox, chemodenitrification and codenitrification. Most nitrogen transformations are microbially driven and are strongly influenced by a range of environmental variables including temperature, pH, and substrate availability. Understanding the precise controls over nitrogen turnover is important as it may ultimately allow the development of specific management practices that can help to mitigate emissions.

Nitrogen fixation and assimilation

Nitrogen fixation is the process by which gaseous nitrogen is converted to NH_3 or NH_4^+ through biological fixation, or NO_3^- through high energy physical processes (for example lightning, volcanic action and combustion). Atmospheric nitrogen is extremely stable, with a strong triple covalent bond, and a large amount of energy is required to break the bonds that hold the two N atoms. Lightning burns at 20,000 °C and is powerful enough to break the bonds of the nitrogen molecule in the atmosphere. Once split, the nitrogen atoms are able to bond with oxygen in the atmosphere, forming NO_2 and NO . These dissolve in precipitation, forming

Table 1 Dominant forms of nitrogen in soils.

Name	Chemical formula
Ammonia	NH_3
Ammonium	NH_4^+
Dinitrogen	N_2
Nitrate	NO_3^-
Nitric oxide	NO
Nitrite	NO_2^-
Nitrogen dioxide	NO_2
Nitrous oxide	N_2O
Organic nitrogen	R-NH_2

Fig. 1 Dominant soil nitrogen transformation pathways.

NO_3^- , which are carried down to the soil surface by atmospheric deposition (for example rain and snowfall). Atmospheric fixation contributes to an estimated 5–8% of the total nitrogen fixed.

A greater amount of biologically available nitrogen, however, is naturally generated through the biological conversion of atmospheric nitrogen to $\text{NH}_3/\text{NH}_4^+$. Biological nitrogen fixation (BNF) results in nitrogen gaining electrons and is termed a reduction reaction (Eq. 1). The capability to fix nitrogen is found only in certain bacteria and archaea, and more than 90% of all nitrogen fixation is affected by these organisms. There are two main groups of nitrogen-fixing bacteria. The first are the free-living (non-symbiotic) bacteria, which includes the cyanobacteria and genera such as *Azotobacter* and *Clostridium*. The second group includes the mutualistic (symbiotic) bacteria, such as *Rhizobium*, which are associated with leguminous plants and *Azospirillum*, which are associated with cereal grasses. The *Rhizobia* interact with leguminous plants to form root nodules within which conditions are favorable for bacterial nitrogen fixation which the host plant can use. However, successful symbiosis requires the partners (plant and bacteria) to be compatible with each other throughout the process of symbiotic growth. Nonetheless, incompatibility regularly occurs, whereby a bacterial strain is unable to nodulate a certain host plant or form nodules that are able to fix atmospheric nitrogen.

The NO_3^- and NH_3 resulting from the nitrogen fixation process are assimilated into the specific tissue compounds of algae and plants. Animals then eat these algae and plants, incorporating them into their own body compounds.

Nitrogen mineralization and immobilization

Nitrogen mineralization is the process by which organic nitrogen present in materials ranging from manures to crop residues are transformed to inorganic (or mineral) forms, including NH_3 , NH_4^+ and NO_3^- . During amination, the first step in nitrogen mineralization, larger macromolecules of organic nitrogen compounds are degraded into smaller simpler organic compounds (for example amino acids, sugars and nucleic acids; Eq. 2). During subsequent ammonification, amino groups (R-NH_2) are converted to NH_3 , in a reaction carried out exclusively by heterotrophic microorganisms (Eq. 3). Rates of mineralization depend on soil temperature, moisture content, and aeration. Mineralization is generally coupled with immobilization which operates in the reverse direction. Immobilization can be achieved through either biotic or abiotic processes. During biotic immobilization (the dominant form of immobilization particularly in agricultural systems), NO_3^- and NH_4^+ are taken up by soil microorganisms making them unavailable for plant growth, and thereby returning them to organic compounds. This process, however, is temporary as when microorganisms die, organic nitrogen is gradually converted back to plant-available forms through mineralization and nitrification. Mean turnover times for microbial biomass nitrogen have been estimated at up to 2 months (Davidson et al., 1992). The availability of organic carbon to soil microorganisms for decomposition is generally considered to determine the immobilization capacity of soil nitrogen. Substrates with high carbon to nitrogen ratios (for example straw) can increase biological activity resulting in a greater microbial nitrogen demand, and thereby enhance rates of nitrogen immobilization. This underlines the close coupling between nitrogen and carbon cycling in soils. During abiotic immobilization, inorganic nitrogen can fix to clay minerals in a relatively rapid process. Abiotic immobilization is particularly common in forests and semi-arid grasslands, among other ecosystems (Moritsuka et al., 2004).

Ammonia and ammonium

The NH_3 and NH_4^+ forms exist in equilibrium in the soil, with the balance of each largely determined by soil pH. The relative concentration of NH_3 increases with increasing pH above 7, while NH_4^+ concentration decreases. Volatilization is the loss of nitrogen through the conversion of NH_4^+ to NH_3 gas. It occurs when NH_4^+ at the soil surface is converted to NH_3 gas at high soil pH. Rates of NH_3 volatilization increase at higher soil pH, as elevated H^+ concentrations promote the conversion of NO_3^- to NH_4^+ . Major factors that regulate NH_3 emissions include soil properties (primarily pH), temperature and soil moisture, and the timing and type of fertilizer application (primarily by affecting NH_4^+ concentrations). For example, NH_3 volatilization is greater from ammonium sulfate ($(\text{NH}_4)_2\text{SO}_4$), and urea applications than from NH_4NO_3 . Of these, urea is the most widely-used fertilizer, accounting for nearly 30% of all global fertilizer sales. When applied to soils, up to 50% can be volatilized. Globally, NH_3 volatilization is a major pathway of nitrogen loss and may account for up to approximately two-thirds of applied nitrogen from synthetic fertilizers. The NH_3 emissions from agricultural fields can be deposited in nearby ecosystems, driving eutrophication. Some NH_3 can also be oxidized and converted to nitric acid which contributes to acid rain. Alongside the adverse environmental impacts, ammonia volatilization represents a potentially substantial economic loss for farmers. As a result, a range of potential mitigation options have been proposed, including the use of non-urea based fertilizers, fertilization of lower soil horizons, combining applications with amendments, and the use of urease inhibitors (Pan et al., 2016).

Urease inhibitors are often applied with additions of urea to reduce ammonia emissions. These are generally structural analogs of urea and therefore act as competitive inhibitors for hydrolysis by soil urease. This delays the formation of NH_4^+ from urea, and thereby reduces the number of co-occurring areas of high pH and large NH_4^+ concentrations which are optimal for NH_3 volatilization (Harty et al., 2016).

Nitrification

Nitrification is the biological oxidation of NH_3 or NH_4^+ to NO_2^- and subsequently NO_3^- , occurring under aerobic conditions. In agricultural soils, NH_4^+ is rapidly converted to NO_3^- resulting in relatively low concentrations of NO_2^- . In general, NO_2^- does not accumulate in soils except under specific, temporary conditions where the activity of NO_2^- oxidizers is inhibited. This can occur following the application of high concentrations of urea or anhydrous NH_3 fertilizers that can inhibit NO_2^- oxidation due to their toxicity, or by lowering pH (Somers et al., 2019). Nitrification ultimately can lead to N_2O production, and NO_3^- leaching, and can result in the loss of up to 50% of plant available nitrogen in soils (Beeckman et al., 2018). Nitrogen losses of this magnitude result in agriculture being a major contributor to climate change, and the eutrophication of water bodies.

In autotrophic nitrification, ammonia oxidizing bacteria (AOB) convert NH_4^+ to hydroxylamine and then to NO_2^- (Eq. 4). Examples of AOB include *Nitrosomonas* and *Nitrospira*. Ammonia oxidizing archaea (AOA), examples of which include *Nitroso-sphaera*, can also oxidize NH_4^+ to NO_2^- although by a distinct metabolic pathway. The NO_2^- oxidizing bacteria, such as *Nitrobacter* and *Nitrospira* subsequently convert NO_2^- to NO_3^- (Eq. 5). Some *Nitrospira* bacteria have also been found to undertake complete NH_3 oxidation to NO_3^- , in a process known as comammox (Van Kessel et al., 2015). Some heterotrophs have also been reported to carry out nitrification, albeit at lower rates, and primarily in acidic soils (Sahrawat, 2008).

The rate of nitrification in soils is determined by a combination of substrate availability, environmental conditions (for example pH and oxygen availability), and the abundance of specific microbial communities. The availability of NH_3 and/or NH_4^+ often limits the rate of nitrification. Similarly, the absence of oxygen (for example in highly waterlogged soils) can limit the abundance of nitrifier communities. Nitrification occurs within a narrow range of pH (6.6–8.0) as the process is restricted to a limited range of microbial species, with a strong decline below pH 5.5. High rates of nitrification, particularly due to fertilizer applications and leaching of NO_3^- can result in the acidification of soils, necessitating the management of agricultural soils through liming. Nitrification is sensitive to temperature changes across a range of soil types, with optimum temperatures specific to a given environment (Norton and Ouyang, 2019).

Nitrification inhibitors are frequently combined with fertilizer applications to delay the oxidation of NH_4^+ by the soil nitrifier community. This results in a temporary accumulation of NH_4^+ and reduces losses of nitrogen through denitrification and leaching, thereby increasing the efficiency of fertilizer applications. Dicyandiamide (DCD) is one of the most widely used nitrification inhibitors in agriculture because it is relatively cheap, and water-soluble thereby allowing easy application (Harty et al., 2016). The benefits of nitrification inhibitors are partially dependent on the environment (for example pH and texture) and other additional management factors (for example nitrogen fertilization rate).

Denitrification

Denitrification involves the reduction of NO_3^- and NO_2^- to nitric oxide, N_2O and N_2 , under anaerobic conditions. Alongside annamox, it is one of the few pathways by which reactive forms of nitrogen can be converted back into nitrogen gas. In general, denitrification requires available electron donors, such as organic carbon compounds, and available nitrogen oxides (for example NO_3^-) as terminal electron acceptors. The rate of denitrification, and the ratios of the main products (N_2O and nitrogen gas) are largely controlled by interactions between soil properties (particularly availability of mineral nitrogen and labile carbon) and microbial communities, and further mediated by management and climate (particularly temperate which affects microbial activity). Complete denitrification to nitrogen gas is driven by high soil temperatures and water contents, neutral to slightly basic soil pH, low rates of O_2 diffusion and the presence of a labile carbon source (Saggar et al., 2013).

During denitrification, nitrogen oxides are reduced following the addition of two electrons per nitrogen atom, with each step regulated by distinct reductase enzymes coded for by specific genes. The NO_3^- is reduced to NO_2^- by nitrate reductase (Nar) before further reduction by nitrite reductase (Nir) (Eqs. 6 and 7). Nitric oxide is then reduced by nitric reductase (Nor) encoded by the *cnorB* or *qnorB* gene, resulting in N_2O production (Eq. 8). Nitric oxide reductase (Nos) further reduces this to nitrogen gas (Eq. 9). Denitrification genes are named for their enzyme products. Nar is regulated by *narG* or *napA* genes; Nir is regulated by *nirK* or *nirS* genes; Nor is regulated by *cnorB* or *qnorB* gene; and Nos is regulated by *nosZ*. The abundance and activity of *nirS*, *nirK* and *nosZ* genes has previously been proposed as a potential indicator for overall denitrification activity in soils, with high ratios of (*nirK* + *nirS*)/*nosZ* gene copies associated with increased potential N_2O production. Genes involved in denitrification are activated sequentially, with Nar activated within 2–3 h, Nir between 2 and 12 h, and Nor between 24 and 48 h, in response to the addition of carbon substrate under anaerobic conditions. Each enzyme in denitrification requires various metal cofactors. For example, Nor requires copper (Cu), highlighting the important role of the element in denitrification.

Denitrifiers are diverse and include bacteria, archaea, and eukarya, with over 60 genera of bacteria and archaea alone identified as capable of denitrification. All eukaryotic denitrifiers, and the majority of prokaryotic denitrifiers are heterotrophs. However, many lack one or more enzymes required for complete denitrification. Most fungi and a third of bacteria lack Nor, resulting in substantial N_2O production versus nitrogen gas (Philippot et al., 2011).

A range of environmental factors has been identified as regulating soil denitrification, including NO_3^- concentrations, oxygen availability (through determining redox conditions), carbon availability, and temperature (O'Neill et al., 2020). Soil NO_3^- concentrations depend on mineralization and nitrification rates, the presence of plants (i.e. plant nitrogen uptake), immobilization, and NO_3^- losses through leaching and diffusion. Soil NO_3^- is also an important factor in regulating $\text{N}_2\text{O}:\text{N}_2$ ratios. Higher NO_3^- concentrations usually result in increased $\text{N}_2\text{O}:\text{N}_2$ ratios due to the suppression of Nos at higher concentrations (Saggar et al., 2013).

As denitrification can only occur under anoxic conditions, oxygen availability, and by extension soil moisture, is a key factor in regulating rates. Below certain thresholds, largely dependent on soil type, denitrification rates appear unrelated to soil water content, but thereafter rapidly increase with increasing soil water. Low rates with increased oxygen concentrations arise from the inhibition of the reductase enzymes. The ratio of $\text{N}_2\text{O}:\text{N}_2$ also generally decreases with increasing soil water content/decreasing soil oxygen, with 75% water-filled pore space identified as an important threshold. Management practices that impact soil oxygen supply and/or soil moisture can therefore have a significant impact on rates. Compaction from grazing or the use of heavy farm machinery can restrict soil oxygen diffusion, thereby enhancing denitrification. Similarly, rainfall events can affect rates of soil denitrification directly, through altering soil moisture content, but also indirectly by increasing soil carbon mineralization and releasing trapped soil gases.

The optimum pH for denitrification is between 7 and 8 but can still occur at more acidic pH. Denitrification has also been reported at pH values as low as 3.5 and can therefore still account for significant nitrogen losses in naturally acidic soils. At lower soil pH the $\text{N}_2\text{O}:\text{N}_2$ ratio is increased, although the underlying mechanisms remain to be clarified. Nos activity has been found to be reduced at lower pHs, and possibly reflects increased fungal dominance. Increasing soil pH may therefore represent an important mechanism to reduce field emissions of N_2O , although Nor is increasingly inhibited, resulting in increased production of N_2O versus N_2 (i.e. increased $\text{N}_2\text{O}:\text{N}_2$ ratios). Heterotrophic denitrification is frequently limited by the availability of labile carbon. Consequently, processes that influence the rate of carbon mineralization and/or immobilization in soils (such as drying and rewetting cycles, residue or fertilizer additions or root exudates) can significantly affect rates of denitrification. Generally, increasing soil organic carbon decreases $\text{N}_2\text{O}:\text{N}_2$, although the effect of carbon availability on fluxes has also been shown to depend on both NO_3^- concentration and soil moisture content. Rhizosphere soils have been suggested as having reduced $\text{N}_2\text{O}:\text{N}_2$, most likely resulting from increased available carbon from root exudate input, although other factors including soil pH and oxygen availability may be involved.

Denitrification occurs across a range of temperatures, with optimal temperatures of approximately 30 °C. However, as the denitrifying microbial communities can adapt to changes in soil temperature, different regions have been reported to have varying optima. In addition, directly regulating rates of microbial activity, temperature can indirectly affect denitrification through its influence on gas solubility and diffusion rates, and availability of the required substrates. The activation energy for N_2O reduction is greater than that for N_2O production, and therefore some studies have reported decreasing $\text{N}_2\text{O}:\text{N}_2$ ratios with increasing soil temperatures, although this is not a universal finding (Wang et al., 2021).

Codenitrification

Stable isotope experiments with ^{15}N tracers have indicated the potential importance of codenitrification as an additional, although understudied, nitrogen transformation pathway (Clough et al., 2017). During codenitrification (also referred to as biotic nitrogen-nitrosation), organic nitrogen compounds (for example amines) are co-metabolized with an inorganic nitrogen source to produce N_2O and gaseous nitrogen under neutral to alkaline conditions. During codenitrification, the hydrogen atom in the organic compound is replaced with a nitroso group ($-\text{N}=\text{O}$) and is catalyzed by enzymatic nitrosyl compounds which attract a variety of nucleophilic co-metabolites including hydroxylamine, NH_4^+ , hydrazine, amino compounds, and NH_3 . The products contain one nitrogen atom from both the organic and inorganic nitrogen sources. Significant rates of codenitrification are only likely to occur when nucleophile concentrations are at least one order of magnitude greater than that of NO_2^- or nitric oxide (Spott et al., 2011). Theoretically, the environmental controls over denitrification also apply to codenitrification, although there have been relatively few studies conducted to date which demonstrate this. The contribution of codenitrification to soil N_2O fluxes has been estimated at between 13% and 90% (Clough et al., 2017; Selbie et al., 2015).

Chemodenitrification

Chemical denitrification, termed chemodenitrification, is the abiotic reduction of inorganic nitrogen under anaerobic conditions. During the process, NO_2^- reacts with ferrous iron (Fe^{2+}) and water to produce N_2O and Fe^{3+} . The presence of Fe^{2+} is driven by heterotrophic Fe^{3+} reducing microorganisms, as well as by the availability of NO_2^- , produced during the reduction of NO_3^- during denitrification, thereby underlying the close relationship between iron redox cycling and the nitrogen cycle. The extent of N_2O

production by chemodenitrification compared to denitrification is relatively poorly understood although it has been suggested that it may account for between 31% and 75% of total N_2O production in agricultural soils (Venterea, 2007).

Dissimilatory nitrate reduction to ammonium

Dissimilatory nitrate reduction to ammonium (DNRA) is an aerobic form of respiration by a number of groups of heterotrophic bacteria and some fungi. These bacteria use NO_3^- as a terminal electron acceptor when oxidizing soil organic matter. In the wider nitrogen cycle, this pathway therefore bypasses denitrification and nitrogen fixation by producing NH_4^+ . However, the process is often overlooked in descriptions of the soil nitrogen cycle, primarily because it is generally considered to occur only under highly reducing soil conditions (for example in flooded environments). The ^{15}N stable isotope tracing, however, suggests that DNRA can be the dominant NO_3^- consumption process under certain circumstances.

Anammox

While the majority of nitrification is carried out under aerobic conditions, anaerobic NH_4^+ oxidation (anammox) can also occur, mediated by a limited number of bacteria within the phylum *Planctomycetes* (Strous et al., 1999). Although initially identified in a wastewater treatment process, anammox bacteria have subsequently been reported across a range of soil types and soil conditions, including rice paddies and arable upland soils. The NH_4^+ and nitrogen dioxide are converted to nitrogen gas and water under anoxic conditions. First, NO_2^- is reduced to nitric oxide by nitrite oxidoreductase (nir), before being combined with NH_4^+ to form hydrazine by hydrazine synthase (hzs). This is oxidized by hydrazine oxidoreductase (hzo) to dinitrogen gas. Relationships between rates of nitrogen loss through anammox and specific management interventions (for example fertilizer applications) remain poorly understood compared to other nitrogen transformation pathways. Anammox bacteria can tolerate large soil NH_4^+ concentrations and may be an important nitrogen loss pathway under certain circumstances, for example ranging from 3.15–9.62% in a rice–wheat rotation (Gu et al., 2017).

Measuring and monitoring human impacts on nitrogen cycles

Anthropogenic impacts on the soil nitrogen cycle

Anthropogenic activities have dramatically increased concentrations of N_2O in the atmosphere, from 291 ppb in 1960 to 330 ppb in 2017, and are greatly increasing the amount of nitrogen cycling between soil, water, and the atmosphere (Fig. 2). In many ecosystems, the supply of nitrogen is a key factor controlling the nature and diversity of plant life, the population dynamics of grazing animals and their predators and essential ecological activities such as plant productivity and the cycling of carbon and soil minerals. Excessive nitrogen can pollute ecosystems (for example eutrophication), drive soil acidification and result in substantial in gaseous emissions, collectively resulting in a change ecological functioning and potentially the communities they support.

Soil acidification is a major problem identified with the excessive addition of soil nitrogen. Acidification can result in the leaching of cationic nutrients including potassium (K^+), sodium (Na^+), calcium (Ca^+) and magnesium (Mg^+). Collectively, this leads to a reduction in plant productivity, and can affect the balance of nitrogen transformation pathways and therefore gaseous emissions. The NO_3^- , as a highly mobile compound that can leach downwards into the groundwater, particularly if the groundwater is shallow and the underlying soil type is sandy. Leaching into larger water bodies can result in eutrophication resulting in excessive growth of weeds and algae, and can contaminate drinking water supplies.

Most anthropogenic effects on the nitrogen cycle are highly local in scale, although can have global effects. For example, studies in pasture systems have frequently reported that most nitrogen losses through denitrification occur following fertilizer additions, primarily because nitrogen availability represents the most important limitation on denitrification. There is therefore significant

Fig. 2 Rise in atmospheric N_2O concentrations (ppm). Data from Dlugokencky (2020).

spatial variation in N_2O emissions, particularly under grazing where urine and manure inputs lead to emission hotspots. The extent of losses are in large part determined by the quantity of nitrogen applied (for example if it is being applied in excess of crop demand), the type (for example urea or NH_4NO_3), and the inclusion of any inhibitors of nitrogen turnover. An example of a widely used nitrification inhibitor is dicyandiamide (DCD).

In addition to agriculture, other local activities that include burning of fossil fuels, power generation plants, and industries can also be a significant source of atmospheric nitrogen. Large applications, often in excess of agronomic need, have resulted in a surplus of nitrogen with major and long-term environmental consequences for large regions of the Earth.

Quantification of soil nitrogen transformations and emissions

A range of methodologies has been proposed for quantifying key soil nitrogen transformation pathways, but key challenges remain in terms of distinguishing dominant transformation pathways (Fig. 3). Denitrification is particularly difficult to quantify because of considerable spatial and temporal variation, and challenges in quantifying its end-product (N_2). In particular, the 'hotspots' and 'hot moments' concept, whereby relatively small areas become substantial $\text{N}_2\text{O}/\text{N}_2$ sources for brief periods of time can make capturing emissions challenging without continual measurements. Difficulties in quantifying processes and emissions result in subsequent problems in modelling and scaling fluxes.

The use of ^{15}N stable isotope labelling has been widely adopted in the literature as a standard technique for assessing soil nitrogen turnover. Across two studies in 1954–1955, Kirkham and Bartholomew developed the isotope pool dilution technique allowing the quantification of nitrogen transformation rates. When combined with modern ^{15}N tracing models, the approach can be crucial for disentangling previously poorly understood pathways (for example codenitrification). In addition to quantifying nitrogen transformation rates, ^{15}N labelling is also useful for partitioning N_2O emission sources (for example the balance of nitrification versus denitrification). The ^{15}N labelling also allows the quantification of soil-derived N_2 , against high atmospheric background concentrations. This is particularly important in the context of mitigating substantial GHG emissions from agriculture, as it allows the assessment of the impact of different practices on $\text{N}_2\text{O}:\text{N}_2$, and therefore the identification of management approaches that can divert N_2O to N_2 (Van Groenigen et al., 2015). Alongside ^{15}N tracing, the use of oxygen isotopes (^{18}O) as an additional tracer allows the further separation of pathways, specifically NH_4^+ derived N_2O emissions from NH_4^+ oxidation versus nitrifier–denitrification (Kool et al., 2011). Acetylene (C_2H_2) has also been used to quantify gaseous nitrogen emissions because it can inhibit denitrification. This allows the indirect estimation of N_2 production without the use of stable isotope techniques which can be prohibitively expensive (Felber et al., 2012). However, there is a range of limitations including incomplete inhibition due to diffusion barriers in soils, suppressed microbial respiration (Groffman et al., 2006). Such techniques can be particularly powerful when coupled with characterizations of soil microbial community structure and function. For example, quantification of denitrifiers can be achieved using real-time quantitative PCR, focussing on nirK, nirS, and nosZ (Jones et al., 2014).

Several studies have undertaken direct field measurements of gaseous nitrogen emissions. Many have used static chambers because of the ease of measurement and potential for large scale replication. However, static chambers are generally poor at capturing the temporal and spatial variation of emissions, resulting in over- or under-estimates of N_2O emissions. Alternative approaches are predominantly based on micro-meteorological techniques, the most well-known and widely-used example of which is eddy covariance. This approach allows the continuous measurement of N_2O fluxes at ecosystem scales, which theoretically provides additional insights into factors that regulate N_2O emissions, and the underlying soil nitrogen transformation processes (Liang et al., 2018). Satellite derived data are becoming increasingly available, including for nitrogen emissions, offering an important opportunity for helping to close emissions budgets.

Fig. 3 Methodologies for quantifying soil nitrogen transformations and emissions.

Future research directions and conclusions

Research priorities for soil nitrogen

Ongoing environmental issues continue to arise from large inputs of nitrogen in excess of crop and soil demand, and potential feedbacks from climate change may substantially impact the terrestrial nitrogen cycle. Continued research focussing on developing more effective nitrogen management, particularly in agriculture, is therefore urgently required. Potential practices of note include those often grouped as regenerative agricultural management, encompassing organic nitrogen fertilizers, biofertilizers, the incorporation of crop residues and the use of biochar. Many terrestrial systems also remain relatively understudied in terms of the nitrogen cycle. Examples include tropical wetlands, which evidence suggests may be a substantial N_2O source (D'Amelio et al., 2009). While the majority of research on soil nitrogen transformation pathways continues to focus on nitrification and denitrification, the importance of other processes (for example codenitrification) remain relatively understudied, despite evidence suggesting they may make a substantial contribution to nitrogen turnover (Spott et al., 2011). Moreover, our understanding of species and individual plant-level controls over nitrogen cycling (for example the contributions of root turnover and root exudation of carbon and nitrogen to nitrous oxide emissions) remains relatively limited in a number of ecosystems. Finally, potential climate feedbacks must also be considered. This includes understanding the combined effects of warming and changes in precipitation, and alterations in soil moisture regimes across a wide range of ecosystems, from agriculture to forests (Wang et al., 2021).

Conclusions

Nitrogen is among the most important nutrient for plant growth and as such is heavily applied to agricultural soils to maintain crop yields. Application rates, however, are frequently in excess of crop demand, resulting in large rates of loss and negative environmental impacts. Mitigating these adverse effects requires a detailed understanding of the nitrogen transformation processes that occur in soil systems. Soil nitrogen turnover is dominated by a series of processes beginning with mineralization whereby organic forms of nitrogen are made available for plant uptake. Nitrification and denitrification convert NH_4^+ and NH_3 to NO_2^- , NO_3^- and ultimately N_2O and N_2 gases. During immobilization, microbial communities can take inorganic forms and fix them in the microbial biomass. A growing number of techniques, often coupled to new modelling approaches, are now available and are increasingly being used to understand both the scale of nitrogen turnover in soils, and opportunities for mitigation.

Abstract

Phosphorus (P) in soil derives from weathering of primary minerals, such as apatites, present in almost all types of rocks, globally ensuring its availability for plants. In natural systems, P availability depends on a concerted interaction between abiotic processes – sorption/desorption, precipitation/dissolution, leaching and runoff – and biological processes – microbial mineralization/immobilization, plant uptake and organic P recycling–. However, the P cycle has been largely modified by anthropic actions, leading to an uneven P distribution in global soils that can increase the global imbalance in P-cycling and food production. The sustainability of future agricultural production requires that P recovery from wastes is improved, losses to water systems are limited and the availability of legacy soil P is enhanced.

Glossary

1:1 Al silicates Secondary phyllosilicates whose crystals comprise an alternating tetrahedral sheet (silicon and oxygen ions) bonded to an octahedral sheet (oxygen, aluminum, and hydroxyl ions) with a 1:1 ratio.

Fe and Al oxi(hydr)oxides Different pools of minerals including oxides, hydroxides and oxy-hydroxides of iron (Fe) and aluminum (Al).

Inner-sphere complex Type of surface complex with direct bonding between the surface and the adsorbed molecule, without interposition of water molecules.

Mycorrhizae Symbiotic association between fungal hyphae and plant roots. Ectomycorrhizae, the fungal hyphae do not enter the root cells; arbuscular mycorrhizae, the fungal hyphae enter plant cells forming vesicles and ramified structures for nutrient exchange; ericoid mycorrhizae, intraradical coils of hyphae in the outermost layer of root cells.

Myo- and scyllo-inositol hexaphosphate Two isomers of phytic acid, general formula $C_6H_{18}O_{24}P_6$, a P reservoir in bran and seeds.

Outer-sphere complex Type of surface complex where the adsorbate retains its hydration shell, water molecules are interposed between the surface and the adsorbate which is retained through electrostatic interaction.

Point of zero charge The pH value at which the net total charge of the surface of a colloidal particle is equal to zero.

Key points

- Soil P is essential for life
- Abiotic processes dominate in P rich soils while biological processes become essential in P poor soils
- The P cycle has been largely modified by anthropic actions
- Global imbalance in P stocks, cycling and food production need to find new integrated solutions that improve P recovery from wastes, limit losses to water systems and enhance the availability of legacy soil P

Introduction

The cycle of phosphorus (P) in ecosystems differs from those of carbon (C) and nitrogen (N), which have much faster cycles. The dynamics of P can be treated as one-way traffic from rock deposits to waters and sediments, as a full cycle would take millions of years to complete. Phosphorus in soil derives from weathering of primary minerals, such as apatites, present in almost all types of rocks, globally ensuring its availability for plants. Phosphorus is essential to all forms of life and constitutes about 0.2–0.5% of plant dry weight, where it is primarily a component of tissue molecules such as nucleic acids, phospholipids, and inositol phosphates. After nitrogen, P is the second most limiting nutrient: it can reduce plant growth and development and potentially limit crop yield. In natural systems, P availability depends on a concerted interaction between abiotic processes such as mineral weathering, sorption/desorption, complexation, precipitation-coprecipitation/dissolution, leaching and runoff of P compounds bound to soil colloidal surfaces, and biological processes including microbial mineralization/immobilization, mobilization of organic P, and plant uptake and recycling. However, the P cycle has been largely modified by anthropic actions, including mineral and organic fertilization. In many agricultural soils this has caused an excess of P, which can be detrimental to the environment because P can enter freshwater bodies through surface runoff and cause algal bloom reducing water quality. On the other hand, the large use of P fertilizers implies a flux of P from countries rich in P ores or deposits to developed areas, increasing the global imbalance in P stocks, cycling and in crop productivity. This highlights the need to find new integrated solutions that can improve not only P cycling in anthropic systems, but must also consider the mining and industrial processes of P fertilizer, the food/feed chain production, and management of P-containing wastes.

Phosphorus forms in soils

In the soil–water–plant–atmosphere continuum of terrestrial ecosystems over 90% of the P is stored in soil, while freshwaters and the atmosphere contain only very small P concentrations. In plant tissues, P concentrations are less than those of nitrogen (N), potassium (K) and calcium (Ca).

The weathering of phosphate minerals represents the primary source of P in soils. This source is only slowly renewable, since the slow abiotic cycle closes with soil renewal as a consequence of pedogenetic factors, or with tectonic uplift, that bring new minerals to the soil in geological timescales. In contrast to the slow geochemical cycle, internal biotic cycling is much faster, leading to the buildup of sparingly available organic P forms. Therefore, the disruption of P cycling in agricultural soils can lead to long-term P depletion of the system (Fig. 1).

Fig. 1 Phosphorus cycle showing the flux of P from primary minerals into the soil solution; abiotic processes including adsorption/desorption and precipitation/dissolution; biotic processes, including microbial immobilization/mineralization and plant uptake; anthropic actions, including crops and livestock, that change P inputs/outputs; runoff and leaching with transfer of P from soil to waters.

Fig. 2 The global distribution of total P in soil showing a latitudinal gradient with decreasing content from high to low latitudes (unit: g P m^{-2}). Adapted from Yang X, Post WM, Thornton PE, and Jain A (2013) The distribution of soil phosphorus for global biogeochemical modeling. *Biogeosciences* 10: 2525–2537.

Soil phosphorus content can vary widely, in the range $50\text{--}3000 \text{ mg kg}^{-1}$, depending on the type of parent material, pedogenesis, and land use. In general, soil P content is lowest in tropical regions, where soils (i.e. Ultisols) have gone through millions of years of soil development and have lost most of their original P through leaching or erosion, and highest in Inceptisols and Entisols of colder regions (Yang et al., 2013; Fig. 2).

The proportion of organic and inorganic P forms varies with time and with soil environments; the organic fraction ranges between 20 and 80% of the total. It commonly increases in surface soil layers compared with deeper ones, together with the concentration of organic matter. It can become the dominant form in soils of moist, cool climates with thick organic layers, before the total P content begins to decline, and strongly fixed, poorly available forms become prevalent (Fig. 3). Conversely, in deeper soil layers, particularly in young soils of temperate and dry regions, inorganic P forms largely prevail.

Inorganic P mainly derives from the weathering of primary minerals, mostly in the form of apatite, a mineralogically complex compound with the empirical formula $\text{Ca}_{10}(\text{PO}_4)_X\text{X}_2$ ($X = \text{F}^-, \text{Cl}^-, \text{OH}^-, \text{or } \text{CO}_3^{2-}$). The content of Ca-phosphates in soil parent material can vary depending on the kind of bedrock. Within igneous rocks, total P content generally increases from silica-rich rocks, such as rhyolite and granite (median, $310\text{--}440 \text{ mg kg}^{-1}$), to iron-rich ones, such as basalts and alkali basalts (median, 920 to $>2000 \text{ mg kg}^{-1}$). However, across all rock types, ultramafic igneous rocks, such as peridotite (median, 120 mg kg^{-1}) have the lowest P content. Sedimentary rocks have P contents that decrease with increasing grain size ($1100\text{--}500 \text{ mg kg}^{-1}$), while carbonate rocks have generally lower P concentrations (Porder and Ramachandran, 2013). As mineral weathering and soil development proceeds, the P in primary apatites dissolves and, if not taken up by soil biota or leached to the water system, it is adsorbed or (co) precipitated with Fe and Al compounds, becoming in general sparingly soluble.

The fraction of organic P increases during the development of natural soil systems to a maximum, where it can encompass 80% of the total soil P, then it begins to decline, while changing its composition (Turner et al., 2007). The organic forms of P found in soil reflect the composition of the soil biome and of the P-bearing biomolecules derived from the decomposition of plant and microbial debris. However, their proportion varies compared with those found in living cells, depending on their lability and rate of degradation (George et al., 2018). Nucleic acids and phospholipids represent the most abundant forms of P in living cells, whereas in soils they form only about 2 and 5%, respectively, of the total organic P, and monoesters can represent over 50%. Phosphate monoesters, in particular inositol phosphates, such as *myo*- and *scyllo*-inositol hexaphosphate, accumulate in soils since they are protected against degradation by forming stable surface complexes with Fe and Al ox(hydr)oxides and 1:1 Al-silicates, or insoluble precipitates with iron, aluminum and Ca. The main organic forms of P that can be found in living organisms and soil are shown in Fig. 4.

Abiotic processes controlling P availability

Phosphorus is known to be relatively immobile in the soil environment because, differently from N, it forms stable complexes with soil solid phases and or sparingly soluble precipitates with Fe, Al or Ca. For this reason, its concentration in the soil solution is generally lower than those of other macronutrients, ranging between 10^{-8} and 10^{-5} M (Frossard et al., 1995). The partition of soil P

Fig. 3 Conceptual model modified from Walker and Syers (1976) showing variation in soil P pools with time: total soil P; Ca-P: calcium phosphates; organic P; occluded P; nonoccluded P. The model suggests that highly weathered soils have less total P, higher relative proportions of occluded and organic P compared to less developed soils. Modified from Walker TW and Syers JK (1976) The fate of phosphorus during pedogenesis. *Geoderma* 15: 1–19.

Fig. 4 Main organic P forms present in living organisms and in soil.

Fig. 5 Abiotic and biotic processes controlling the availability of P for plant uptake. Sorption processes are reported in order of increasing retention from the physi- and chemi-sorbed pools to occluded ones and from precipitated as poorly crystalline hydroxides, crystalline oxides, to coprecipitates and insoluble minerals. Biotic processes include immobilization of P distributed in different organic forms.

among more or less mobile fractions, which can be taken up by plants or move to different environmental compartments (such as ground and surface waters) depends on the mechanisms controlling the equilibria between the forward and backward direction of three couples of reactions, i.e., adsorption/desorption, precipitation/dissolution, and immobilization/mineralization by soil biota. The major factors controlling such equilibria are soil pH, redox conditions, contents of Fe and Al oxy(hydr)oxides and 1:1 Al-silicates, presence of competing solutes, organic matter and other environmental factors affecting soil microbial activity (Fig. 5).

Adsorption and desorption reactions

In developed soils, phosphorus limitations to plant growth can largely derive from the build-up of the inorganic and organic P pools adsorbed on the surfaces of Fe and Al oxy(hydr)oxides and clay minerals. In principle, phosphate anions can adsorb as outer-sphere complexes to any positive site of soil solid phases. However, phosphate can replace structural singly coordinated surface hydroxyls on Fe and Al mineral surfaces forming inner-sphere complexes, and this binding mechanism is considered dominant in acid soils (Arai and Sparks, 2007). Phosphorus species adsorbing with the inner-sphere mechanism can form monodentate, bidentate binuclear, or bidentate mononuclear complexes in different proportions depending on the chemical species of P involved, pH and surface coverage. Inorganic phosphate seems preferentially to form bidentate, binuclear complexes with most Fe oxides (Fig. 6), although monodentate chemi-sorption and physi-sorption are also proposed as potentially important mechanisms (Fig. 5).

Adsorption is the dominant mechanism for P retention operating in acid and subacid soil environments, where variably charged minerals mostly display positively charged surfaces, which favors anion adsorption. The ability of such minerals to deplete the soil solution of inorganic and organic P species depends on their surface area and point of zero charge (e.g., Celi et al., 2020). Thus, poorly ordered minerals with a large specific surface area can sequester more P than well crystallized oxides, for which the specific surface can decrease over one order of magnitude during crystal growth. Different Fe minerals with similar specific surface areas, but with different surficial hydroxyl configurations, such as goethite and hematite, can display different P adsorption capacity. Phosphate adsorption on variably charged surfaces decreases as pH increases because of the reduction in positively charged sites, and with a marked decrease above their point of zero charge. In soils with pH close to, or above neutrality, the adsorption of low concentrations of P on Ca and magnesium (Mg) carbonates can occur, whereas P sequestration from the solution of calcareous soils following large P additions mainly depends on other mechanisms such as its precipitation as sparingly soluble Ca salts. Soil organic molecules can offer positively charged sites for P adsorption, such as protonated amino groups, however, the dominant net negative charge displayed by soil organic matter hampers the adsorption of large amounts of anionic species. In contrast, low molecular weight organic acid anions are known to promote phosphate desorption, competing for the same binding sites on positively charged surfaces and displacing the adsorbed P species. Thus, the input of organic amendment can improve phosphate availability in soils with high P-fixing capacity, and the production of low molecular weight organic acids (e.g., oxalic, citric, malic, etc.) by plant roots and soil microorganisms is an important tool for improving P availability. However, this depends on the forms of P, with inositol phosphates being retained more than P diesters and inorganic phosphate (Fig. 6). It has been observed that the reversibility of P adsorption on Fe and Al minerals diminishes with age of the P-surface bonding, resulting in substantial hysteresis of P

Fig. 6 Adsorption mechanisms of P on Fe oxy(hydr)oxides via (i) a bidentate binuclear ligand exchange mechanism (inorganic phosphate and organic P monoesters), and (ii) a monodentate mononuclear ligand exchange mechanism (organic P diesters). The retention of organic P compounds on mineral surfaces reduces phosphatase activity and inhibits phytase activity. Plant and microorganisms can produce protons, organic acid anions and electron donors to release the organic P compound from minerals for enzyme hydrolysis and favor plant P uptake.

adsorption/desorption curves. This is possibly explained by slow diffusion processes of the adsorbed P into the solid phase, with increasingly scarce availability of legacy phosphorus in agricultural soil (Smolders et al., 2021).

In soils of arid environments, P is commonly less mobile than in those of moist climates. In addition to the slower dissolution of primary phosphate minerals, this depends on the increased pore volume occupied by the soil solution and consequent dilution effect, which enhances P transfer from the solid to liquid phase. Soil moisture also stimulates the activity of soil organisms, accelerating the solubilization of P that derives from the decomposition of organic moieties, as well as the formation of soluble organic molecules. The release into solution of the P adsorbed on Fe minerals is markedly enhanced in submerged soils. The anoxic conditions are accompanied by a decrease in soil redox potential, which causes the reductive dissolution of Fe oxides, starting from the scarcely crystalline forms that have a large active surface. In such soils, the fate of P is closely related to the Fe redox wheel, and conditions that favor a rapid Fe dissolution enhance a correspondingly fast release of P in solution. Conversely, soil drainage and the establishment of oxidizing conditions determine the precipitation of Fe oxy(hydr)oxides and the re-immobilization of P on these solid phases. In periodically submerged soils, such as paddy rice fields, the availability of soil P is closely related to water management practices, with a marked increase in P availability to plants following soil submersion. When reducing conditions persist for a long time, the formerly dissolved P can adsorb on the residual surfaces of non redox-sensitive minerals, as well as on newly formed minerals, including mixed-valence Fe compounds such as green rusts, thus limiting in time the effects of Fe reductive dissolution on P concentration in soil solution.

Solubilization and precipitation reactions

Available soil P in principle originates from the dissolution of primary P-bearing minerals, mainly represented by apatites. Apatite dissolution is favored by moist climates, accumulation of organic matter and sub-acidic pH conditions. In addition to the dissolving effects of a sufficient water content in soil, the presence of organic matter promotes the activity of the soil biome and production of

Fig. 7 Retention of inorganic P as a function of soil pH: at low pH P is precipitated as Fe or Al salts, and bound to Fe, Al and Mn oxy(hydr)oxides. As pH increases, P can be bound to phyllosilicates, whereas at pH > 7 P is immobilized as calcium phosphate. The actual proportion of P that remains in an available form is in the narrow pH range between 5 and 7.

organic acids. The latter may decrease the activity of metal cations in solution (including Ca^{2+} , Mg^{2+} and other ions), enhancing the dissolution of primary apatites. Moreover, the release of carbon dioxide with microbial respiration increases the acidity of soil porewater (Frossard et al., 1995; Hinsinger, 2001). In alkaline, carbonate-rich soils, dissolved P forms can be subtracted from solution by the precipitation of secondary Ca-phosphates. This mechanism is governed by soil pH, the solubility of Ca-phosphates increasing as pH decreases, while their precipitation is enhanced with increasing P concentrations (e.g., following P fertilization) and metal ion activity in the soil solution.

In acid soils, P can precipitate with Fe and Al, forming minerals such as vivianite, strengite, variscite; in contrast to Ca-phosphate, the solubility of Fe- and Al-phosphates tends to decrease with increasing soil acidity. The contrasting effect of pH on the solubilization of Ca-phosphates vs Al- and Fe-phosphates, together with the maximum adsorption of P on mineral surfaces when pH is acidic, explains why the optimum soil pH range for P availability to plants is around neutral (pH 6 to 7, Fig. 7).

In soil, secondary P precipitates often display a weak crystalline order because of the presence of dissolved organic molecules and other solutes that hamper the crystallization. However, with time, they tend to evolve to more crystalline forms and become progressively less soluble, which further reduces P availability for plant uptake (Hinsinger, 2001). Organic P forms, such as inositol phosphates, can form secondary precipitates with metal oxides as for phosphate ions. Considering the large concentration that dissolved Fe^{2+} ions can reach in anoxic soils, the precipitation of Fe—P compounds can represent a significant P sink in submerged environments (Santoro et al., 2019). Surface precipitation of organic and inorganic P compounds can also occur after P adsorption on calcite, as well as on Fe and Al oxy(hydr)oxides, particularly with large concentrations of dissolved P (Arai and Sparks, 2007). This phenomenon involves multilayer adsorption and tridimensional growth of the adsorbate on the adsorbent surfaces. While bulk precipitation occurs when the adsorbate is oversaturated with respect to a solid phase, surface precipitation may occur even if the bulk solution is undersaturated with respect to the solubility product of sparingly soluble adsorbate compounds. The formation of surface precipitates, compared with adsorption, further diminishes the reversibility of P bonding to soil solid surfaces, particularly at high P loadings and prolonged residence times. This has to be considered in planning phosphate fertilization management in agricultural soils.

Biotic processes

Microbial immobilization and mineralization

Microorganisms compete with plants for available P, assimilating and immobilizing the element in their cells to synthesize vital biochemical compounds. This process is particularly important in preventing P leaching or fixation of P on soil surfaces provided the microbes remain alive. With microbial death and senescence, microbial organic P becomes part of soil organic P that can be mineralized and thereby supply the bioavailable inorganic P (Pi) pool.

Microorganisms and plants may also cooperate by modifying the rhizosphere characteristics (e.g. pH, redox conditions, enzyme activity), weakening the strength of bonds between P and the soil matrix, and consequently enhancing P availability. In general, the microbes are an advantage for plants because microorganisms often mineralize organic P compounds for their C

needs rather than P (Spohn and Kuzyakov, 2013). This may first lead to a net P immobilization when plant residues show a $C/P > 300$ (i.e. maize (*Zea mays* L.), rice (*Oryza sativa* L.), pruning residues), which in turn, is followed by a net mineralization when C/P decreases to ≤ 100 , due to decomposition or in species such as alfalfa (*Medicago sativa* L.), sugar beet (*Beta vulgaris* L. var. *saccharifera*), potato (*Solanum tuberosum* L.), which have a large N content. Net P mineralization is also influenced by the degree of maturity of the residue itself, contact time with soil, and by the amount of inorganic P initially available for microbial immobilization. Net P mineralization can create an extra P pool for plants although physicochemical processes may mask or dominate microbial P mineralization process. This occurs especially in P-rich soils where rates of gross P mineralization represent a small percentage of P exchanged by physicochemical processes. Conversely, in P-poor soils with a low P-sorbing capacity, microbial P mineralization may dominate over other processes and primarily contribute to the available P pool (Fig. 8).

Input of organic C into soil by litter or root exudates strongly shapes P immobilization/mineralization processes by microorganisms, acting directly on microbial activity or changing the environmental conditions for enzyme reactions. Root exudates can stimulate microbial gross P mineralization and phosphatase activity. The mineralization of organic P compounds may be determined by the C requirements of the microbial community (Spohn and Kuzyakov, 2013), decoupling P mineralization rates from those of C. In P-poor soils, it becomes important to add organic matrices, such as compost, manure, and biowastes to supply nutrients and reduce competition for P reserves between plants and microorganisms. As for nitrogen, synchronization between crop residue or compost addition and fertilization can optimize P availability to plants, keeping in mind that in many biowastes P exceeds crop needs (Fig. 8).

The equilibrium between P immobilization and mineralization can be affected by changes in temperature and soil moisture. In cool climates, low temperatures constrain biological activity, resulting in more organic P but less microbial P than in temperate regions. In temperate regions, seasonality strongly affects microbial P cycling with a larger microbial uptake during the spring–summer time (Bol et al., 2016). In warmer regions a fast biocycling of microbial P is essential to prevent strong limitation of P availability due to the dominance of retention processes, as described above. With climate change, soils subject to progressive drying may exhibit slower microbial P mineralization because water limitation may reduce enzyme activity. Conversely, drastic short-term drying and re-wetting events may cause the release of P through microbial cell lysis.

Plant nutrition and strategies of plants to acquire P

Phosphorus accounts for 0.2–0.5% of the plant dry weight and is an essential macronutrient, playing a fundamental role in the plant cell, as a constituent of DNA molecules at the genetic level, by entering into the composition of membrane phospholipids at the structural level, and in the form of adenosine triphosphate (ATP) at the energetic level. In plant metabolism, P promotes various functions such as cell division, flowering, fruit and seed formation, ripening, root development, and resistance to cold and pest attacks. In cases of P deficiency, which occurs when P in tissues is $<0.1\%$, the plant suffers a reduction in both root and shoot

Fig. 8 Microbial immobilization/mineralization as a function of C needs: net P immobilization occurs when plant residues show a $C/P > 300$ causing a decrease of available P in the soil system; net P mineralization occurs with $C/P \leq 100$ resulting in an increase of available P.

Fig. 9 Shoots and root details of tomato plants grown in conditions of P sufficiency (A, B, C) and P deficiency (D, E, F). The leaves of P-deficient plants show a dark-bluish coloration with subsequent reddening of marginal areas (D and E) and the root (F) shows ultrastructural disturbance, such as the elongation of the meristematic zone along the longitudinal axis. Photos by Dr. Veronica Santoro.

growth, and delays in flowering and fruiting that affect the quantity and quality of production. The shoot/root ratio decreases and leaves, especially the older ones, turn into a dark-bluish-green color with subsequent reddening and necrosis of marginal areas. Excess P has no direct consequences, but it causes lower uptake of some microelements such as zinc (Zn), copper (Cu) and Fe. Therefore, a proper balance between deficiency and excess must be maintained (Fig. 9).

In contrast to the diversity of P pools present in soil, the only form taken up in significant amounts by plants is orthophosphate, which is mediated by dedicated P_i transporter proteins. However, because of the low solubility of sorbed and mineral-bound P, phosphate concentrations in the soil solution are generally relatively small. Available P in the soil solution is taken up by the plant by mass flow, which is a mechanism that creates a flux of water and ions to the roots, but is negligible for phosphate nutrition. More important is the diffusion mechanism: the plant absorbs phosphate because of the decrease in P concentration around the root, creating a concentration gradient that allows P to flux from more concentrated areas toward the root (Fig. 10). The plant can absorb P from its surroundings through an active process that occurs at the expense of respiration and is more pronounced in acidic pH soils. Transport of P across membranes occurs mainly by specific transporter proteins, mostly as co-transport with protons. Translocation of P_i in the xylem is mainly controlled by the difference in water potential between leaves and the soil. Relocation in the phloem can occur as P_i or organic P compounds such as ATP or hexose phosphate, all are highly mobile in this vascular tissue.

To avoid P starvation plants have developed various strategies, which can be subdivided into foraging (moving toward nutrients) and mining (mobilization of poorly available resources) (Richardson et al., 2011). The first strategy is based on the modification of the root architecture, investing a greater proportion of plant biomass in the root system and enlarging the surfaces by root hairs. Adaptations of root architecture that enable greater exploration of the soil volume and or the mining of localized patches of relatively high P availability include inhibition of primary root growth, promotion of lateral root growth, enhancement of root hair development and cluster root formation. An additional major reaction of plants to low nutrient availability is the formation of arbuscular-, ericoid- or ecto-mycorrhizae with respective fungal partners. These lead to increased plant development and vigor due to a high efficiency in P uptake even where available forms are scarce. The second strategy includes root-induced changes in the rhizosphere (Hinsinger, 2001). Roots can acidify the rhizosphere and promote P release from soil surfaces and plant uptake. In addition, plants can improve their capacity to scavenge for P through the release of organic acid anions, particularly citrate, oxalate and succinate, that can compete with phosphate for the same sorption sites. These anions can also increase P availability in acid soils by complexing Fe and Al. In neutral or calcareous soils, acidification increases the solubility of Ca phosphates (Fig. 10).

Roots may also exude low-molecular weight phenolic acids that can contribute indirectly to mobilize P by reducing Fe-containing minerals to which P is associated.

Fig. 10 Processes controlling P dynamics at the soil–plant interface: by desorption, solubilization and mineralization, phosphate can be released from bulk soil and diffuse toward the depletion zone. Plants and microorganisms can exude organic acid anions, protons, enzymes and electron donors to favor the release of P from bulk soil.

Enzyme concentration is generally greater in the rhizosphere than in the bulk soil (Nannipieri et al., 2011). Enzymes are often assumed to be produced mainly by root-associated microorganisms, but plant roots can also contribute (Richardson et al., 2011). Phosphorus bound in organic compounds can be mineralized by phosphatases, comprising phospho-monoesterases (including phytases), phospho-diesterases, triphospho-monoesterases and enzymes acting on phosphoryl-containing anhydrides and on P–N bonds (Nannipieri et al., 2011). An important difference concerns the generally most abundant group of phospho-monoesterases, which can be acid or alkaline according to their pH-optimum. While the former are produced by all relevant organisms including plant roots and ectomycorrhizal hyphae, the latter are mainly produced by free living microorganisms. The pH value may also affect the distribution of other P hydrolyzing enzymes.

Although phosphatase activity in soils is governed to a large degree by the homeostatic behavior of microorganisms and the related strongly constrained enzyme acquisition ratios, there is also clear evidence for the strong effects of P and N availability. While an increase of P availability by P fertilization leads to a reduction in phosphatase activity, aggravation of P limitation by N fertilization or N deposition leads to an increase in phosphatase.

Soil phosphatase activity varies strongly spatially in soil. Spohn and Kuzyakov (2013) showed that phosphatase release at the rhizoplane can differ from that in the extended rhizosphere in terms of pH optimum and dependence on P availability. Although mobilization of P through the abovementioned mechanisms increases P availability for plants and microorganisms, it rarely increases phosphate concentration in the soil solution. Thus, the depletion zones around roots that are created by P_i uptake may not be replenished sufficiently fast by P_i because of its low mobility and strong affinity to the solid phase. Thus, organisms need to take up mobilized P directly to avoid losses to high affinity sorption sites of the soil solid phase. Therefore, the generally more mobile dissolved organic P may be critical for replenishment of the rhizosphere, where it is mineralized by phosphatases in the rhizoplane. Phosphatase may further assist plant nutrition through enhanced recycling of internal P and efficient capture of organic P compounds that may be lost from roots (Richardson et al., 2011).

To what degree are the interactions between plant and microorganisms mutualistic or competitive with regard to P? There is some evidence that plants might be able to stabilize mutualism. For example, under P deficient conditions where the roots are colonized simultaneously by several species and/or genotypes of mycorrhizal fungi, plants can direct C flow to more beneficial mycorrhizal symbionts. While the role of mycorrhizal hyphae in mobilizing sorbed and bound P_i is well established, their involvement in the mineralization of organic P and bioweathering of more recalcitrant P from minerals is, in most cases, poorly quantified. The role of P mobilizing compounds released by non-symbiotic rhizosphere microorganisms for plant nutrition and how this depends on interactions with roots and hyphae is also poorly understood. Because microorganisms require homeostasis, the status of microbial P may be more important for P mobilization in the rhizosphere than the plant P status. The activity of free-living rhizosphere microorganisms may therefore support plant nutrient uptake or compete with it. The search for supporting plant-growth promoting microorganisms is of great current interest for improving P availability for plants.

Losses of P from soil

Phosphorus continues to be a significant threat to global water quality. Rosemarin (2004) estimated that about 25% of the 250×10^6 tons of P extracted from phosphate ores since 1950 is immobilized in the soil or has been delivered to waters. This has led to widespread eutrophication problems because P is the limiting nutrient for algal growth. Eutrophication, that is, the progressive increase of aquatic organisms due to nutrient enrichment, is one of the most important phenomena of environmental degradation related to anthropogenic activities. In a eutrophic waterbody, as a result of the accelerated and abnormal growth of algal and plant biomass, most of the balances in the trophic chain are modified by a significant impoverishment of biodiversity and the impairment of those services and uses (drinking, bathing and tourist use, fishing) associated with surface water quality.

The poor availability of P for crops, due to biotic and abiotic immobilization processes that occur in the soil, and the low cost of phosphate fertilizers has led, since the Second World War, to an excessive use of fertilizers with the result that many soils of industrialized countries are overfertilized. The diffusion of intensive and often specialized farming systems with a growing imbalance between livestock load and cultivated areas where manure could have been distributed is leading farmers to add more P than the crop needs. Imbalance in the manure N/P ratio with P in excess compared to plant needs, has focused mainly on N in the context of legislation, and further contributes to P overfertilization.

Nowadays, point-source nutrient emissions have been reduced with the enlargement of sewage systems, P removal from municipal and industrial effluent, and changes in industrial processes. Thus, agriculture is now considered the main source of P pollution for waters.

Phosphorus in soil is vulnerable to mobilization during storm flow events or during irrigation, and is subsequently delivered to the watercourses. Transfer into waters also occurs through erosion, runoff or leaching as particulate or soluble P. Losses occur more by runoff than by leaching and particulate P is often the major form of P transported from cultivated soils, representing up to 80% of total transported P. Conversely, runoff from uncultivated soils generally moves little sediment, and P losses are generally dominated by dissolved P. Runoff involves mainly the surface soil layer down to 5 cm, and the subsurface if impermeable layers are present. In a catchment there are only a few areas, the so-called 'critical source areas' (CSA), that provide the vast majority of P (Gburek and Sharpley, 1998). These critical areas are influenced by two interdependent factors: (i) source factors, indicating areas that undergo large P accumulation and that consequently represent a great potential for contributing to P export, and (ii) transport factors that depend on the interaction between landscape and climate.

The processes that mobilize added and native P in soils are solubilization and detachment. Solubilization indicates P transfer from a solid phase: at the normal concentration of soil solution P, desorption is generally more important than dissolution or mineralization of organic matter in regulating soluble P concentration. Detachment produces particulate P: this process brings into suspension soil aggregates, primary particles and P-associated colloids (Fig. 11). The controlling mechanisms are mechanical forces exerted by moving water and repulsive forces between soil particles having the same electrical charge.

Soils with a low P sorption capacity, i.e. sandy or organic soils poor in sorbing constituents, can be easily saturated. Under these conditions P concentration of the soil solution could be quite large and is ready for transport by both leaching and runoff. However, P leaching is effective only in sandy, well drained soils and with large volumes of incoming flow. Under these conditions, the risk of P losses can be estimated by the degree of P sorption saturation (DPSS), i.e. the ratio between the previously sorbed P and the P sorption capacity of the soil:

$$DPSS = P_{ox} / (Al_{ox} + Fe_{ox}),$$

where DPSS is the degree of P sorption saturation, P_{ox} , Al_{ox} and Fe_{ox} are the amounts of P, Al and Fe extractable with acid oxalate buffer.

Fig. 11 Dispersion of clay particles because of P retention: clay particles are in general aggregated in most soils; P sorption can cause a reversal of charge producing coulombic repulsive forces that favor particle dispersion and mobilization during runoff with consequent transfer of particulate P from soil to waterbodies.

This index is based on the assumptions that P-sorption capacity is determined by poorly crystalline Fe and Al oxi(hydr)oxides and that P extracted by oxalate represents the P reversibly sorbed by the soil. This approach is reasonably accurate for acid and coarse-to-medium textured soils in humid regions, but it fails to explain the behavior of soils with different mineralogical characteristics. For example, it fails in calcareous soils or in soils where P sorption is determined mainly by crystalline Fe oxides, carbonates and silicate clays; it requires modified equations to calculate the DPSS as a function of the different soil mineralogy.

Particle detachment, responsible for losses of particulate forms, occurs through a combination of physical and chemical factors. The main physical factors are rain splash energy, slaking forces of wetting fronts, and the shear forces of overland flow. The chemical factors are related to the accumulation of P in the finest soil particles and to the equilibrium between particle dispersion and aggregation. Factors that affect soil P sorption capacity such as clay and organic matter content, control its accumulation in the finest particles. In turn, P sorption influences the surface charge of the sorbent particles and may even cause a reversal of the positive charge of Fe and Al oxi(hydr)oxides, increasing the electrostatic repulsive forces and enhancing soil particle dispersion (Fig. 11). The detachment and subsequent settling of soil particles results in selective transport of the finest microaggregates and primary particles within water flows. This indicates that total soil P content is not a good index for predicting P losses because the P accumulated in fine particles depends on soil texture rather than on soil total P content, with the highest values in sandy soils (Fig. 12). Thus, tests based on soil dispersibility are useful for predicting P transfer in particulate form and for comparing the vulnerability to P losses of different soils.

As P losses depend on the combination of source and transport factors, all management practices that limit P input, favor particle aggregation or reduce surface runoff can be effective in limiting P losses. Because soil P surpluses are caused by unbalanced fertilization plans, all new integrated multifunctional solutions that combine plant needs and soil properties with a correct fertilization plan and better utilization of legacy P are efficient ways to protect water resources.

Phosphorus resources and global fluxes

Phosphorus is the thirteenth most abundant element in the Earth crust and is a structural and functional component of all organisms. It is an essential nutrient, necessary for growth and development of plants and animals on which our food supply depends. There are no substitutes for P as a plant nutrient, therefore, P fertilizers are required to sustain high crop productivity and quality to provide sufficient food for a rapidly growing world population.

Phosphorus fertilizers are produced from finite, irreplaceable, non-renewable resources, estimates of which are largely uncertain. Rock phosphates can be classified as (i) reserves, i.e. a resource base that is likely to exist, and with production costs that allow current economic extraction, (ii) reserve base: based on probability of occurrence and production costs, including those resources that are currently economic, marginally economic or sub-economic; and (iii) additional resources, i.e. undiscovered resources and unconventional occurrences that can be used in case of future scarcity (Van Vuuren et al., 2010). The U.S. Geological Survey (USGS, 2008) reported a world reserve of almost 18 Gt phosphate rock and a reserve base (including reserves) of 51 Gt.

High-grade ores are concentrated in a few countries: Morocco and Western Sahara control 71% of the world's phosphate, and China, Egypt, Algeria, Brazil, and South Africa 17% (USGS, 2022). while China (53.43%), United States (11.13%), Morocco and Western Sahara, Russia and Jordan are responsible for the 83% of the world's annual production of phosphate rock (USGS, 2019), leaving importing countries vulnerable to geopolitically induced scarcity.

The risk of depletion of P resources has been studied by numerous authors (i.e. Cordell et al., 2009) who, with various mathematical models, have predicted a risk of phosphate rocks exhaustion within a few decades or, at most, within 1–2 centuries. The main difficulties in estimating when phosphate rocks will be depleted is largely due to uncertainties in quantifying the amount of phosphate rocks available in North Africa and China, the increasing fertilizer demand from countries that do not currently use fertilizers, and changes in food that significantly increase the meat-based diet in developing countries. In 2014, P was included in the European Union's list of critical raw materials (CRMs, 2014).

In the pre-industrial period, societal production, processing and consumption of food, feed and fiber were closely related in space and time. Phosphorus, which was removed from the soil with crops from agricultural production areas, was compensated for by regular flooding or shifting cultivation, or was supplemented by P in manure from livestock grazing on surrounding rangeland. Waste products containing P (manure, crop residues, human waste) were sufficient to improve or maintain soil fertility to produce reasonable yields, closing the P cycle. The introduction of fertilizers led to agricultural intensification and specialization, which allowed the human population to grow and afforded humankind a more affluent diet. However, it also led to less recycling of waste streams back to the sites of production, causing imbalances between oversupplied regions and regions where soils are mostly P-deficient. Phosphate fertilization started around the 1850s and rapidly increased after World War II with the Green Revolution. World fertilizer production reached $22.4 \cdot 10^6$ tons in 1988 and then sharply declined by 30% in the 1990s due to both political-economic problems in former USSR countries and to environmental policies, especially in Europe and US to reduce eutrophication problems. Since 2001, however, fertilizer production began to increase again, and today about $18.5 \cdot 10^6$ tons of phosphate rock (about 89% of the amount mined) are used annually for fertilizer production or animal feed.

The global cropland area amounts to $1.6 \cdot 10^9$ ha (FAO, 2021), with an estimate of average P fertilizer application of 10 kg ha^{-1} but very large differences among continents (e.g. 3 vs 25 kg ha^{-1} in Africa and Europe, respectively) and even within the same continent (e.g. 34 and 7 kg ha^{-1} in Ireland and Sweden, respectively). This means that, in contrast to areas that continue to be severely overfertilized, there are large areas, mainly in Africa, South America and some parts of Asia, where soils are often naturally P-poor and already suffer from fertilizer shortages, resulting in poor agricultural productivity and further depletion of soil nutrient reservoirs. Farmers in these countries will be unable to cope with further unavoidable cost increases when phosphate resources begin to run out.

An adult consumes $300\text{--}450 \text{ g P year}^{-1}$ depending on whether his or her diet is vegetarian or includes foods of animal origin: thus, about $3.1 \cdot 10^6$ tons P are required for human nutrition every year, a figure that continues to rise as the world population increases. Comparison of this number with the $18.5 \cdot 10^6$ tons of phosphate rocks designated for agricultural production shows clearly the enormous inefficiency of P use in the food production chain: only about a sixth of the P contained in mined phosphate rocks is consumed in food. The main causes of P inefficiency are due to P transfer from soil to waterbodies by erosion or leaching, accumulation in soil, losses throughout the food chain, and during extraction from mines and processing (Cordell et al., 2009). In addition, close to 100% of P eaten in food is excreted, about 50% of which is in urine and feces, with an average recovery of only about 10% on a worldwide basis; again with enormous differences among countries (Fig. 13).

Concluding remarks

From this analysis, we can infer that significant losses occur throughout the system, from mine to field, to fork. This shows that to address simultaneously phosphate scarcity and water pollution from P leakage, we must adopt an integrated approach that cannot involve only agricultural production and the food supply chain, but must also consider the mining and industrial processes of fertilizer and feed production, and the management of P-containing wastes. To reach this aim, we can work in at least four directions: (i) improving the efficiency of converting phosphate rock into fertilizer; (ii) minimizing phosphorus losses from the farm; (iii) minimizing losses in the food commodity chain; (iv) upcycling alternative renewable P sources, like manure, human excreta and food residues, v) find new mechanisms to reduce overall P demand (Cordell and White, 2011). Implementing these measures will inevitably require an integrated approach that looks beyond the current focus on reducing agricultural P leakage into waterways. This suggests: (i) calibrate soil P inputs; (ii) develop innovative agronomic technologies, including genetic selection; (iii) integrate agricultural and livestock systems in efficient circular systems; (iv) minimize the transfer of P from soil to water by favoring crop P uptake; (v) recover P from urban wastewater with the emphasis to urine; (vi) decrease P losses and improve P recovery throughout the food chain; (vii) influence diet choices; (viii) improve techniques for P extraction; and (xi) develop new technologies for the production of biowaste-derived P biofertilizers.

Fig. 13 Phosphorus availability bottlenecks: physical, economic, social and ecological factors limit the availability of P for productive use by humans for fertilizers and hence food production. Abstract

Soil aluminum (Al) fractions are reviewed in relation to their representative constituents, characteristics, and their extractants. For the Al species in soil solution, the formation constants of Al with ligands, including OH[−] (hydroxyl ion), F[−] (fluoride ion), phosphate ions, and organic ligands, are summarized. For the Al species in soil solids, the dissolution constants of Al-containing minerals are also summarized, and dissolution diagrams based on the constants are shown to explain a general method to identify soil components responsible for controlling Al concentration in soil solution. In addition, technical problems on Al speciation in soil environments are referred to with possible clues for improvement in future research.

Glossary

Mononuclear Al species A molecule containing one Al atom in its chemical structure.

Polynuclear Al species A molecule containing two or more Al atoms in its chemical structure with Al—O(H)—Al bond.

Key points

This article provides information on:

- (1) elemental properties of Al
- (2) Al species in the solid phase of soils
- (3) Al species complexed with inorganic ligands in the solution phase of soils
- (4) Al species complexed with organic ligands in the solution and solid phases of soils
- (5) soil components controlling Al concentration in the soil solution, and
- (6) technical problems in Al speciation in soil environments.

Introduction

Aluminum (Al) is the third most abundant element in the Earth's crust (mean: 8.2%) and in soils (median: 7.1 to 7.2%) after oxygen (O) and silicon (Si). Because the solubility of Al in water is very low, most soil Al exists in the solid phase, i.e., primary minerals, secondary minerals, and Al-organic matter complexes (Table 1). The relative mobility of Al in landscapes is lowest among common elements in the Earth's crust and in the following order: Cl (chloride) > SO₄ (sulfate) > Na (sodium) > Ca (calcium) > Mg (magnesium) > K (potassium) > Si (silicon) > Fe (iron) > Al (Hudson, 1995). Therefore, the content of Al in soils will increase with the progress of soil formation and weathering.

When Al dissolves in solution and exists as Al³⁺, it exerts an inhibitory effect on the growth and development of many organisms, including higher plants, soil microorganisms, phytoplankton, fish, and other aquatic animals (Parker, 2005). The solubility of Al in water is strongly affected by solution pH. In acidic soils with soil pH(H₂O) range between 4 and 5, the reduction of plant production can be mostly ascribed to Al toxicity rather than H⁺ (hydrogen ion) toxicity. Therefore, it is important to understand the chemical forms of Al in solution in relation to its solubility, pH, origin of the dissolved Al, and interactions of dissolved Al species with other ligands to form complexes. Basic knowledge of the elemental properties of Al will be of help to understand the principle of Al behavior in soils.

Elemental properties of aluminum

In nature, Al has only one stable oxidation number of +III and two stable coordination numbers of 4 and 6. Here, the coordination number stands for the number of anionic atoms (mostly O atoms in nature) bonded to the Al atom. The stereo structures of Al with the coordination numbers of 4 and 6 are the tetrahedron and octahedron, respectively (Fig. 1). In aqueous solution, tetrahedral Al is possible when all of the surrounding O atoms form the hydroxo ion (OH⁻), forming [Al(OH)₄]⁻. When one or more of the surrounding O atoms form(s) the aquo ion (H₂O), Al takes the octahedral structure, forming [Al(H₂O)₆]³⁺, [Al(H₂O)₅(OH)]²⁺, [Al(H₂O)₄(OH)₂]⁺, [Al(H₂O)₃(OH)₃]⁰, and polynuclear Al species. Therefore, the stereo structure and the chemical form of Al in aqueous solution depend strongly on the pH of the solution.

Table 1 Soil Al fractions related with representative constituents, characteristics, and extractants.

<i>Al fractions</i>	<i>Representative constituents</i>	<i>Characteristics</i>	<i>Representative extractants</i>
Al in solution	Monomeric Al species such as [Al(H ₂ O) ₆] ³⁺ , polymeric Al species	Directly toxic to organisms	Water
Al attracted electrostatically	[Al(H ₂ O) ₆] ³⁺ adsorbed electrostatically on negatively charged sites	Toxic after released into solution	Salt solutions (e.g., 1 M KCl)
Al-organic matter complexes	Al coordinated with carboxylic (COOH) groups with ligand exchange reaction	Stabilize soil organic matter	0.1 M pyrophosphate solution
Al in hydroxides and poorly crystalline minerals	Gibbsite, poorly-ordered Al hydroxides, allophane, imogolite	Secondary minerals	0.2 M acid oxalate solution (pH 3.0)
Al intercalated in the interlayer spaces of layer silicates	Hydroxyaluminum polymer ions, hydroxyaluminosilicate polymer ions	Exist as stable pillared structure	0.3 M sodium citrate at 100 °C
Al incorporated in Fe minerals	Al substituted in the crystal structure of goethite, hematite, and ferrihydrite	Al substituted in secondary Fe minerals	Dithionite-citrate-bicarbonate solution
Al composing 1:1 and 2:1 aluminosilicate minerals	Kaolinite, halloysite, smectite, vermiculite, chlorite	Secondary clay minerals	HF-HCl solution
Al composing primary minerals	Feldspars, pyroxenes, amphibole, volcanic glass	Stabilized in crystal structure	HF-HCl solution

Fig. 1 Stereo structures of (A) tetrahedral Al with coordination number of 4 and (B) octahedral Al with coordination number of 6.

Fig. 2 Amphoteric interface on the surface of gibbsite under (A) high pH and (B) low pH conditions. The interface can possess negative or positive charge depending on solution pH and electrostatically hold ion(s) with opposite charge.

According to the 'electrostatic valency principle' of Pauling's Rules, each of six coordination sites on the octahedral Al should possess a positive charge of 0.5+, because a positive charge of 3+ on the Al atom should be divided equally and distributed at each of the coordination sites ($[3+]/6 = 0.5+$). Therefore, when OH^- and H_2O occupy the coordination site on octahedral Al, the site should possess a negative charge of 0.5- and positive charge of 0.5+, respectively. This phenomenon explains the amphoteric properties of aluminol sites ($\text{Al}-\text{OH}$) coordinated on octahedral Al depending on surrounding pH (Fig. 2). The aluminol site on octahedral Al exists on allophane, imogolite, and the broken edge of 1:1 and 2:1 aluminosilicate minerals and gibbsite. In the case of tetrahedral Al, each of four coordination sites on the tetrahedral Al should possess a positive charge of 0.75+ ($[3+]/4 = 0.75+$). Therefore, each coordination site on the tetrahedral Al possessing OH^- should have a negative charge of 0.25-.

Aluminum species in the solid phase of soils

In most primary minerals in igneous rocks, such as alkali feldspars, plagioclase feldspars, feldspathoids, pyroxenes, amphiboles, and volcanic glass, tetrahedral Al constitutes the basic skeleton of those minerals together with tetrahedral Si by forming an $\text{Al}-\text{O}-\text{Si}$ bond, and octahedral Al is only a minor component if it exists. In magma, which generates all igneous rocks, tetrahedral Al will be much more stable than octahedral Al under high pressure, alkaline and anhydrous conditions. In micaceous minerals, which are primary aluminosilicate minerals incorporating a large amount of OH (hydrous minerals), tetrahedral Al and octahedral Al can dominate the tetrahedral sheet and octahedral sheet, respectively. On the other hand, octahedral Al is the major form of Al in secondary soil minerals, such as gibbsite, kaolinite, halloysite, allophane, imogolite, and Al-organic matter complexes. Under soil forming conditions with normal pressure and temperature in the presence of water, tetrahedral Al in primary minerals will be converted into octahedral Al by chemical weathering. The ratio of octahedral Al to tetrahedral Al can be used as an index of mineral weathering in soils.

Soil Al can be operationally classed into several fractions by chemical extractions (Table 1). Most of the reagents and procedures for dissolving the soil Al fractions are identical to those for dissolving soil Fe fractions. Many types of soil organic matter (SOM) are stabilized and sequestered in soils as Al- or Fe-organic matter complexes, and the proportion of the Al-organic matter complexes is generally higher than that of the Fe-organic matter complexes. The aquo ion (H_2O) group on the octahedral Al on the surface of hydroxides and poorly crystalline minerals (Table 1) is very reactive and easily replaced with ligands, such as organic matter with carboxyl/carboxylate group, hydroxyl group, phosphate/phosphoric acid, and HF/F^- .

Aluminum species complexed with inorganic ligands in the solution phase of soils

The hexaquo Al ion, $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$, is a mononuclear Al species and dominant in simple acidic solutions with $\text{pH} < 4.3$. Here, the mononuclear Al species stands for a molecule containing one Al atom in its chemical structure. The $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ species is toxic to many organisms, and the activity of this species is often best correlated with Al toxicity; no toxic effects of Al have been demonstrated at alkaline pH. The $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ undergoes hydrolysis when solution pH increases, and it generates four

hydroxylated mononuclear species, i.e., $[\text{Al}(\text{H}_2\text{O})_5(\text{OH})]^{2+}$, $[\text{Al}(\text{H}_2\text{O})_4(\text{OH})_2]^+$, $[\text{Al}(\text{H}_2\text{O})_3(\text{OH})_3]^0$, and $[\text{Al}(\text{OH})_4]^-$. The hydrolysis reaction is described as follows:

with overall (cumulative) formation constants (β) of the form:

$$\beta_y = \left([\text{Al}(\text{H}_2\text{O})_{6-y}(\text{OH})_y]^{(3-y)+} (\text{H}^+)^y / (\text{Al}(\text{H}_2\text{O})_6^{3+}) \right) \quad (2)$$

where the parentheses indicate ionic activities. The overall formation constants for the hydrolysis reactions of the mononuclear Al species are listed in Table 2. The overall formation constants are valuable when the total activity of the mononuclear Al species in the solution is given or no polymerization reaction occurs. The polymerization reaction forms Al—O(H)—Al bond, resulting in polynuclear Al species, which is defined as a molecule containing two or more Al atoms in its chemical structure with Al—O(H)—Al bond.

When the OH^- ion is added to a pure Al solution with the OH/Al ratio < 3, a polynuclear Al species having a chemical formula of $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ (Fig. 3) is easily formed in the solution. This molecule is comprised of 12 octahedral Al forming a hollow ball and one tetrahedral Al placed inside of the ball; it is called an Al tridecamer (hereafter Al_{13}) or Keggin polymer of Al. The Al_{13} is soluble in water, toxic to plants, and stable for months or even years in solution (Parker, 2005), but its existence in soils and soil solution are rare (Sparks, 2003; Parker, 2005) because the formation and persistence of Al_{13} are suppressed by ubiquitous components of soils, such as silicic acid, sulfate, phosphate, and organic ligands (Hiradate and Yamaguchi, 2003; Yamaguchi et al., 2004).

Table 2 Hydrolysis reaction of hexaaquo aluminum ion ($[\text{Al}(\text{H}_2\text{O})_6]^{3+}$) and its overall formation constants at infinite dilution at 25°C^a.

Reaction	$\log \beta$
$[\text{Al}(\text{H}_2\text{O})_6]^{3+} \rightarrow [\text{Al}(\text{H}_2\text{O})_5(\text{OH})]^{2+} + \text{H}^+$	-5.0
$[\text{Al}(\text{H}_2\text{O})_6]^{3+} \rightarrow [\text{Al}(\text{H}_2\text{O})_4(\text{OH})_2]^+ + 2\text{H}^+$	-10.1
$[\text{Al}(\text{H}_2\text{O})_6]^{3+} \rightarrow [\text{Al}(\text{H}_2\text{O})_3(\text{OH})_3]^0 + 3\text{H}^+$	-16.8
$[\text{Al}(\text{H}_2\text{O})_6]^{3+} \rightarrow [\text{Al}(\text{OH})_4]^- + 2\text{H}_2\text{O} + 4\text{H}^+$	-23.0

Fig. 3 Chemical structure of $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ (Al tridecamer, Al_{13} , Keggin polymer of Al). Al^{tet} , tetrahedral Al; Al, octahedral Al; O, OH.

Sulfate, fluoride, and phosphate ions have a high affinity to Al, and their overall formation constants with Al are given in Table 2. On the other hand, the Al ion has a low affinity to form complexes with Cl^- , NO_3^- (nitrate ion), and HCO_3^- (bicarbonate ion) (Parker, 2005). On the basis of the high stability of Al—O—Si bond in aluminosilicate minerals in soils, it would be possible to postulate the presence of a molecule containing Al and Si atoms in its structure with the Al—O—Si bond (i.e., hydroxyalumino-silicate ions) in the soil solution (e.g., Inoue and Yoshida, 1990), but the evidence for its existence is not strong. In the interlayer spaces of 2:1 clay minerals, the hydroxyaluminosilicate polymer ions have been reported to exist as pillared components to form 1.4 nm (14 Å) minerals together with hydroxyaluminum polymer ions in acidic soils (e.g., Bautista-Tulin and Inoue, 1997).

Aluminum species complexed with organic ligands in the solution and solid phases of soils

Aluminum has high affinities to form complexes with organic ligands, such as low-molecular-weight organic acids (LMWOA), high-molecular-weight dissolved organic matter, and high-molecular-weight precipitates of SOM. In most cases, carboxyl groups are responsible for the high affinity, and the contribution of alcoholic hydroxyls and amines to the stability is less important in general.

Many LMWOA, such as propionate, succinate, oxalate, malate, and citrate, can form soluble complexes with Al in solution. They are derived from microbes and plants and are reported to reduce the toxicity of Al by forming complexes, because most Al toxicity is ascribed to Al^{3+} and Al complexed with LMWOA is less toxic (Hiradate et al., 2007). The formation constants of the Al-LMWOA complexes are listed in Table 3. However, some of these constants are under discussion and different values have been proposed under the assumption of different chemical reactions and different experimental settings (Parker, 2005).

Table 3 Complexation reactions of Al with Low-Molecular-Weight Organic Acids (LMWOA) and its overall formation constants at $I = 1.0 \text{ mol dm}^{-3}$ ^a.

Reaction	$\log \beta$	Ionic strength	Temperature
Monocarboxylate			
$\text{Al} + (\text{formate}) \rightarrow \text{Al}(\text{formate})$	0.6–1.4	1.0 mol dm^{-3}	25 °C

Fig. 4 Chemical structures of deprotonated forms of Low-Molecular-Weight Organic Acids (LMWOA).

In general, the binding affinities of LMWOA to form complexes with Al are in the following order: tricarboxylates > dicarboxylates > monocarboxylates. Because carboxyl C is one of the major forms of soil organic C and therefore SOM can be regarded as a polycarboxylate, the Al ion is fixed on SOM in the solid phase and also acts as the glue to polymerize and stabilize SOM by forming carboxylate–Al–carboxylate bond. The Al complexed with SOM is called Al-SOM or Al-humus complexes (solid components), and they are the major forms of C sequestered in acidic soils, together with Fe-SOM or Fe-humus complexes. For benzoates and polyphenols, such as salicylate, catechol, pyrogallol, and gallate, much greater affinities to Al have been reported (Table 3 and Fig. 4). All of these organic molecules possess 1-carboxyl-2-hydroxy or 1,2-diol structure on a benzene ring, and these partial structures are responsible for the high affinity to Al. The high affinities reported for these compounds are for fully deprotonated forms and thus their actual affinities in soil environments are much less. Nevertheless, these compounds have been reported to have the ability to form complexes with Al in soils (e.g., Furubayashi et al., 2007). Therefore, when SOM contains 1-carboxyl-2-hydroxy or 1,2-diol partial structure on a benzene ring, the Al ions would be fixed through them.

Soil components controlling aluminum concentration in soil solution

In general, Al concentration (activity) in the soil solution is regulated by the dissolution–precipitation reactions of the solid phase. Soils contain various solids that may supply Al to the soil solution (Table 1). Essentially, the solid with the greatest Al solubility determines the Al activity in the soil solution. In many soils, Al-SOM complexes, Al hydroxides and oxyhydroxides, hollow aluminosilicates, 1:1 layer aluminosilicates, or 2:1 layer aluminosilicates supply Al into the soil solution, and their dissolution reactions are shown with dissolution constants ($\log K_{\text{dis}}^\circ$) in Table 4.

In the cases of Al hydroxides and oxyhydroxides, the Al activity in solution at equilibrium can be estimated with the solution pH. For example, the dissolution reaction of gibbsite in Table 4 can be rewritten as below:

$$\log(\text{Al}^{3+}) = 8.04 - 3\text{pH} \quad (3)$$

Therefore, the relationship between $\log(\text{Al}^{3+})$ and pH is linear as depicted in Fig. 5. The cases of equilibria with amorphous $\text{Al}(\text{OH})_3$ and $\gamma\text{-AlOOH}$ (boehmite) are also shown in Fig. 5.

For the aluminosilicate minerals, in addition to pH, the activities of $\text{Si}(\text{OH})_4^0$ and other chemical species should be taken into account for estimating Al activity in solution. For example, the dissolution reaction of montmorillonite in Table 4 can be rewritten as below:

$$0.29 \log(\text{Mg}^{2+}) + 1.71 \log(\text{Al}^{3+}) + 0.22 \log(\text{Fe}^{3+}) + 3.81 \log(\text{Si}(\text{OH})_4) + 6.76\text{pH} = 2.68 \quad (4)$$

$$0.17 \log(\text{Mg}^{2+}) + \log(\text{Al}^{3+}) + 0.13 \log(\text{Fe}^{3+}) + 2.23 \log(\text{Si}(\text{OH})_4) + 3.95\text{pH} = 1.57 \quad (5)$$

$$\log(\text{Al}^{3+}) + 3\text{pH} = 1.57 - 0.95\text{pH} - 0.17 \log(\text{Mg}^{2+}) - 0.13 \log(\text{Fe}^{3+}) - 2.23 \log(\text{Si}(\text{OH})_4) \quad (6)$$

Therefore, when the pH and the activities of Mg^{2+} and Fe^{3+} of the solution are given, the relationship between $(\log(\text{Al}^{3+}) + 3\text{pH})$ and $\log(\text{Si}(\text{OH})_4^0)$ is linear as shown in Fig. 6. Similarly, the dissolution of the other aluminosilicate minerals together with that of Al hydroxides are depicted in Fig. 6.

Fig. 5 Solubility diagram for amorphous $\text{Al}(\text{OH})_3$, $\gamma\text{-AlOOH}$ (boehmite), and $\gamma\text{-Al}(\text{OH})_3$ (gibbsite) drawn based on the data in Table 4. (Al_{3+}): activity of Al_{3+} in mol L^{-1} . Modified and recalculated from Nordstrom DK and May HM (1996) Aqueous equilibrium data for mononuclear aluminum species. In: Sposito G (ed.) The Environmental Chemistry of Aluminum, 2nd edn., pp. 39–80. Boca Raton, FL: CRC Press; Sparks DL (2003) Environmental Soil Chemistry, 2nd edn. Amsterdam: Academic Press.

This kind of figure is used to estimate the solid phase regulating Al activity in the soil solution and identify the most stable solid phase in soils. The solid phase with the highest $\log(\text{Al}^{3+}) + 3\text{pH}$ value (y-axis) is likely to supply Al to the soil solution, and that with the lowest y-axis value corresponds to the most stable solid phase. Fig. 6 suggests that amorphous $\text{Al}(\text{OH})_3$ will supply Al to the soil solution when the activity of $\text{Si}(\text{OH})_4^0$ is high, but when $\text{Si}(\text{OH})_4^0$ activity decreases and is depleted, montmorillonite will supply Al to the solution. Similarly, Houston black smectite is the most stable solid phase when the activity of $\text{Si}(\text{OH})_4^0$ is high, but when the activity of $\text{Si}(\text{OH})_4^0$ is decreased, kaolinite and gibbsite become the most stable solid phase in the soil system. It is also effective

Fig. 6 Solubility diagram for amorphous $\text{Al}(\text{OH})_3$, $\gamma\text{-Al}(\text{OH})_3$ (gibbsite), imogolite, halloysite, kaolinite, montmorillonite, and Houston black smectite at pH 7 under Fe activity equilibrated with soils ($\text{Fe}(\text{OH})_3(\text{soil}) + 3\text{H}^+ = \text{Fe}^{3+} + 3\text{H}_2\text{O}$, $\log K_{\text{dis}}^0 = 2.70$) and K^+ and Mg^{2+} activities of $10^{-4} \text{ mol L}^{-1}$. Dissolution constants were referred from Table 4. a: $\text{Si}(\text{OH})_4^0$ equilibrated with quartz. b: $\text{Si}(\text{OH})_4^0$ equilibrated with soil SiO_2 . c: $\text{Si}(\text{OH})_4^0$ equilibrated with amorphous SiO_2 . (Al^{3+}): activity of Al^{3+} in mol L^{-1} , ($\text{Si}(\text{OH})_4^0$): activity of $\text{Si}(\text{OH})_4^0$ in mol L^{-1} . Modified and recalculated from Nordstrom DK and May HM (1996) Aqueous equilibrium data for mononuclear aluminum species. in identifying the Al supplier to plot the soil solution data of solution pH and chemical composition on this kind of diagram (Lindsay and Walthall, 1996; Sparks, 2003).

It should be noted that the dissolution constant is obtained under equilibrium conditions, and actual soils do not reach true equilibrium. Thus various minerals coexist in a soil. Furthermore, even if a reactive solid phase exists, the surface cover of the solid will prevent the subsequent reactions to supply Al in soil solution. Surface precipitation and sorption are the possible mechanisms that protect the reactive surface from the subsequent reactions. In surface soil horizons, in particular, SOM would be the important agent acting as the surface protector. The complexing ability and surface protecting characteristics of SOM have not been well understood to date because of the complexity of SOM.

Technical problems in Al speciation in soil environments

In general, the concentrations of Al species in soil solution are low ($\mu\text{mol L}^{-1}$ order or less), and the reactivity of the Al species with other chemical species is high. This situation complicates the quantitative determination of the concentration of each Al species in the actual soil solution. For example, many speciation methods of Al rely on reaction-based mechanisms; chromatography and electrophoresis to separate Al species in a mobile phase, resulting in the alteration of pH and composition of the chemical species of the original solutions. Flow-injection analysis and other kinetic analyses employ reactive ligands, such as ferron, 8-hydroxyquinoline, chrome azurol S, and pyrocatechol violet. It is assumed that certain Al species are measured quantitatively during the reaction time with the reactive ligands and that other less labile species are excluded from the reaction, although the relevance of this assumption is not always guaranteed. Atomic absorption spectroscopy (AAS), induced coupled plasma mass spectrometry (ICP-MS), and induced coupled plasma optical emission spectroscopy (ICP-OES) can determine the total Al concentration with high sensitivity, but they cannot determine the concentration of each Al species separately without pre-treatments. The degree of Al polymerization is also very difficult to determine; chemical analyses and computer simulation models are not very effective for this purpose. It is also difficult to separate dissolved Al from colloidal Al distinctly, because a small colloidal particle can pass through a submicron filter membrane. Information on the interaction between Al species and soil organic matters is still necessary to clarify the stability, solubility, degradability, and chemical form of the complexes. These problems were also raised by Parker (2005) in detail.

It would be valuable to combine several analyses and confirm the results with thermodynamic data by employing computer simulation models (e.g., GEOCHEM-PC, MINEQL+, MINTEQA2, PHREEQC, etc.) for obtaining reliable results. In addition, ^{27}Al nuclear magnetic resonance (NMR) spectrometry, a direct and non-destructive analytical method, is a promising tool for the speciation of Al in soil environments (Hiradate, 2004). For the analysis of solutions in particular, the signals originating from the nucleus of ^{27}Al can be obtained non-destructively by simply introducing the sample solution into the spectrometer and irradiating

radio-frequency pulses without the addition of any chemical reagents at ambient temperatures. The problem in analyzing Al species in solution with liquid-state ^{27}Al NMR is the sensitivity and detection limit; liquid-state ^{27}Al NMR can detect 10^{-4} mol L $^{-1}$ or even lower concentrations of $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ and $[\text{Al}(\text{OH})_4]^-$, but the limit of detection increases to 10^{-3} to 10^{-2} mol L $^{-1}$, and Al may even become undetectable, when ^{27}Al NMR signals are broadened by distortion of the magnetic symmetry of the Al nucleus. This typically happens when $[\text{Al}(\text{H}_2\text{O})_6]^{3+}$ is hydroxylated to form $[\text{Al}(\text{H}_2\text{O})_5(\text{OH})]^{2+}$, $[\text{Al}(\text{H}_2\text{O})_4(\text{OH})_2]^+$, and $[\text{Al}(\text{H}_2\text{O})_3(\text{OH})_3]^0$, and also occurs when Al forms complexes with organic ligands. Therefore, one ^{27}Al NMR spectrum alone may not provide strong evidence, but comparing many ^{27}Al NMR spectra would give stronger evidence to support discussion in some cases. For example, determining changes in Al species with time by liquid-state ^{27}Al NMR multi-spectra was effective to clarify the effect of humic substances on the presence of Al_{13} in solution (Yamaguchi et al., 2004). For the speciation of Al in the solid phase, solid-state ^{27}Al magic angle spinning (MAS) NMR can be applicable. Although the signals of ^{27}Al determined by the solid-state MAS NMR are broader than those obtained by the liquid-state NMR, octahedral Al can be clearly differentiated from tetrahedral Al. It should also be noted that NMR signals are suppressed by the coexistence of paramagnetic materials, such as Fe and Mn. These materials accelerate the free induced decay of NMR signals (shortened relaxation), resulting in extreme broadening of NMR signals.

Summary

Soil Al fractions were reviewed in relation to their representative constituents, characteristics, and extractants. For the Al species in soil solution, the formation constants of Al with ligands, including OH^- , F^- , phosphate, and organic ligands, were summarized. For the Al species in soil solids, the dissolution constants of Al-containing minerals were also summarized, and a dissolution diagrams based on the constants were shown to explain a general method to identify soil components responsible for controlling Al concentration in soil solution. In addition, technical problems in Al speciation in soil environments were pointed out with possible clue of improvement for future study. During the transformation processes of rocks into soils (soil genesis), the chemistry of Al changes dynamically, i.e., coordination number, solubility, chemical form, etc. Because Al has a major impact on chemical, biological, and physical properties of soils, further detailed studies on soil Al need to be performed to understand and manage soils well.

Abstract

Iron in the soil is an essential chemical element that contributes both to the structure of soils and to their organization in landscapes. It plays an essential role as a nutrient for all organisms that feed on soil constituents. The duality of insoluble/soluble and oxidized/reduced redox states of iron is a cornerstone of soil formation both zonally and azonally in all surficial Earth formations. These properties are also essential in the mechanisms put in place by organisms to obtain the quantity of iron they need to live from soils where a priori the bioavailability of iron is low.

Key points

- The duality of insoluble/soluble and oxidized/reduced redox states of iron is a cornerstone of soil formation.
- Iron zonal formation laterites cover about one-third of Earth's continental land area.
- Iron azonal formations are dominated by $\text{Fe}^{3+}/\text{Fe}^{2+}$ seasonal dynamics.
- Fougérite is a mixed FeII–FeIII hydroxide formed in moderate reductive conditions as a layered structure.
- There are two iron uptake strategies: (i) Strategy I in all dicots and non-grass monocots, and (ii) strategy II in other organisms, such as grass monocots, bacteria and fungi.

Introduction

When we look at the soil map on a global scale, we observe that the number of major soil types is limited to about a dozen and that the distribution of these soils is above all latitudinal. This means that the main factor in their evolution is essentially the bioclimatic context (temperature, humidity). In a given climatic zone, influence of the substratum on the nature of the soil constitutes the second factor, and at a very local level landform constitutes the third factor of soil evolution.

In all soil classification systems, iron is used as an indicator of horizon differentiation. Thus, classically, brown, red or yellow colors are associated with iron (III) oxides (*sensu lato*), while gray, blue, green or black colors are associated with iron (II) minerals (sulfides and oxides); the white color is interpreted as an indication of the absence of iron (III) oxides.

Iron also plays an essential role in the life of soils, and more generally in all biological cycles interacting with the soil.

Properties of the chemical element iron (Fe)

Iron, Fe ($Z = 26$, A.M. = 55.85 g mol^{-1}) is a chemical element that is part of the first series of so-called transition elements. Due to the increase in number of protons in the nucleus, the filling of the $3d$ subshell, after the filling of the $4s$ subshell, occurs before the filling of the $3p$ subshell. The five $3d$ orbitals of the transition elements are divided, according to group theory, into two families designated by t_{2g} or t_2 and e_g or e . From the energy point of view, these five orbitals are strictly identical in a metal isolated from any influence of electric and or magnetic fields. But in a crystalline structure, the various d orbitals of a transition atom or ion do not react in the same way simply because of their position in space with respect to the anions located at the vertices of the polyhedra. This leads to changes in the energy level of the orbitals, i.e., lifting of degeneracy in a crystal field (Fig. 1).

Iron is chemically active and forms two major series of chemical compounds: the trivalent iron (III), or ferric compounds and the bivalent iron (II), or ferrous compounds. In these compounds, the iron is mainly in octahedral coordination and sometimes in tetrahedral coordination. When iron is in the form of an Fe^{3+} cation, the d orbitals contain five electrons and, in the form of an Fe^{2+} cation, the d orbitals contain six electrons. Depending on the nature of the crystalline field in which the iron is found, several configurations of distribution of the electrons, called high spin and low spin, on the d orbitals are possible.

Stability of the cation depends both on the crystal field to which it is subjected and on its electronic structure. In the mineral, a compromise is thus established between, on the one hand, the fact that the energy of certain d orbitals is decreased and therefore fills in priority and, on the other hand, that in each orbital, the electrons must remain unique as much as possible because pairing consumes energy (of the same order of magnitude as the break in degeneracy). For example, in the mineral goethite, iron can only occupy octahedral sites, *a priori* ideal sites for the stabilization of Fe^{3+} with a crystal field splitting energy (CFSE) of zero. Because the octahedra have common edges leads to local distortions linked repelling iron cations. These distortions are compensated for either partially by changes in the spin state of the iron or by acceptance in the structure of other metals, such as aluminum. In mixed hydroxides like fougérite, stability of the cations in the octahedra is obtained by each cation of Fe^{3+} being surrounded by only divalent cations, either Fe^{2+} or Mg^{2+} .

Iron oxide formations

By order of abundance in the Earth's surface crust, iron ranks fourth and iron oxides constitute a mineral fraction widely represented in soils and weathering horizons. They are ubiquitous and have significant effects on many chemical processes in soils. They can be distributed diffusely in the profile, or concentrated preferentially in specific horizons in proportions that can exceed 50% of the minerals present; e.g., laterites. They form fine crystals, even nanocrystals, such as those observed in coatings on the surface of large minerals or along old root channels or even dispersed in clays; they can also exist as concretions in cemented aggregates, the size of which can easily reach a few centimeters. The crystal lattice of certain oxides allows the substitution of iron by another metal; 10 metals have affinities with iron and the rates of substitution are often significant, i.e., larger than 10%. Due to their small size, iron oxides have large specific surface areas, thus facilitating their interactions with other soil constituents, for example by adsorption with organic complexes, which are sometimes chelating, and with clay minerals, etc.

In the ferric state, iron is soluble only in extremely acidic environments, pH 2–3. In neutral or alkaline environments, Fe^{3+} is not very mobile and is mainly retained in soil minerals. In the ferrous state, iron also forms oxides, but behaves as a water-soluble cation when anaerobiosis becomes established. For this reason, the $\text{Fe}^{2+}/\text{Fe}^{3+}$ redox couple acts as a powerful driving force in the genesis and structure of soils, by cementation/dissolution of aggregates, by the mobility of Fe^{2+} in landscapes.

We focus here on two types of soils where the main mechanisms involved in the dynamics of iron stand out: (i) an example of a zonal soil, the evolution of which depends initially on climatic conditions, and (ii) an azonal soil observed at all latitudes, the evolution of which depends on local waterlogging conditions.

Zonal soils: Example of tropical/equatorial situations

The characteristic of zonal soils is to develop and change under the action of the climate. This is particularly visible when these soils are subjected to extreme climates (precipitation, temperature) over long periods. These soils are currently observed in very low latitude (equatorial and tropical) or very high latitude (boreal) regions.

Typology of lateritic formations

The word "laterite" is derived from the Latin word "later" because in situ, when moist, laterites can be easily cut into bricks. Then later with drying it becomes a very robust material, widely used in the construction of traditional houses in Mesopotamia, Africa, Brazil or India. In the large intertropical zones, due to intensive leaching, laterites are the major end-product of the weathering

Fig. 1 The geometry of *d* orbitals of the element Fe, breaking of degeneracy of the crystal field in octahedral or tetrahedral coordination of Fe²⁺ and Fe³⁺, and symmetry around the cations in different compounds.

system, which favors the massive accumulation of Fe oxides, relative or absolute and by epigenesis (molecular replacement of one mineral by another). These soils are poor in organic matter, nitrogen, phosphate and calcium, while iron oxides are in excess.

Tardy (1997) estimated that laterites cover about one-third of Earth's continental land area. Lateritic soils form the subsoils of the equatorial forest, savannas and Sahelian steppes that cover most of the land area between the tropics of Cancer and Capricorn. However, laterites can also reflect past weathering conditions, particularly when they occur in present-day non-tropical areas. They can also be formed in geological epochs when the area was near the equator. Thus, present-day laterites that occur outside the humid tropics can be considered to be indicators of climate change, continental drift or a combination of both (Bourman, 1993).

In laterites, two main phenomena participate in the accumulation of iron: (i) a relative accumulation by dissolution and loss of the other elements; (ii) an absolute accumulation, due in particular to the formation and growth of nodules from the matrix (Leprun, 1979). Re-examining the various solums that the latter author observed (Fig. 2) the following remarks can be made:

- In un-weathered bedrocks, whether acidic, metamorphic, basic or ultrabasic, iron is associated with primary minerals and represents a variable percentage depending on the nature of the source rock (1–20% expressed as Fe_2O_3).
- In the context of variegated clays, the plagioclases, K-feldspars, biotites, amphiboles... are increasingly weathered toward the top of the profile, in association with smectites and kaolinites, then kaolinites. Iron is expressed mainly in the form of goethite and hematite. The isovolumetric balance shows strict conservation of the iron content (Millot and Bonifas, 1955).
- In the mottled clay horizon, which represents the next stage of weathering, a first mobilization of iron occurs by redistribution. It is concentrated in sites particularly rich in kaolinite and locally forms reddish to ochre spots. In this horizon, the iron isovolumetric balance is also preserved.
- In the ferricretes, iron accumulates absolutely in the form of nodular “oxides,” which increase in size toward the surface of the solum. The Fe_2O_3 contents then vary between 20% and 60%.

Paragenesis of Fe oxides as an indicator of aridity/humidity

In the context of paleo-climatic reconstructions, the relationships between pedogenesis and climate can be explored by thermodynamic modeling because the durations for establishment of these surficial formations are long enough for equilibria between minerals and climatic conditions to be reached. This is the case, for the parageneses of iron and aluminum oxides observed in laterites in Africa where it is possible to calculate a relationship between the two dominant Fe^{III} oxides (goethite and hematite) in well-drained soils, and pedo-climatic indicators such as climate aridity.

The geochemical system to be considered is the Fe_2O_3 — Al_2O_3 (aluminum oxide)— SiO_2 (silica)— H_2O (water) system for which the domains of stability of the cardinal minerals of lateritic soils can be calculated and represented, namely iron and aluminum oxides and hydroxides. The four main factors that govern the balances between the different minerals are: (i) the water potential (“water activity”), (ii) the temperature, (iii) the chemical composition of the solution (“silica activity”), and (iv) the particle size (differences in solubility products K_{sp}) with the following results (Trolard, 1997):

- At a given temperature, the decrease in water activity (or increase in aridity) leads to the eventual transformation of hydrated minerals into dehydrated minerals, e.g., goethite into hematite, gibbsite into boehmite then gibbsite to corundum or halloysite to kaolinite;
- A decrease in water activity or an increase in temperature have a similar effect on the equilibria leading to the same successions of minerals or parageneses, e.g., in systems with a low aluminum content: $\text{Al-goethite} \rightarrow \text{Al-goethite} + \text{Al-hematite} \rightarrow \text{Al-hematite}$; in systems with high aluminum content: $\text{Al-goethite} + \text{gibbsite} \rightarrow \text{Al-goethite} + \text{boehmite} \rightarrow \text{Al-hematite} + \text{boehmite} \rightarrow \text{Al-hematite} \rightarrow \text{corundum}$.
- In the association (Al-goethite + gibbsite) or (Al-goethite + Al-hematite), the Al concentrations both in goethite and hematite depend only of water activity and temperature: they increase as water activity decreases or as temperature increases;
- The association of Al-goethite and Al-hematite with kaolinite induces significant decreases of Al/Fe ratios in the Fe-Al oxides; these correlate with both increases of water and silica activities.

Thus, the diagrams of the domains of stability of the different oxide parageneses are consistent with the pedoclimatic zoning observed in the natural laterites (Fig. 3), thus establishing the link between the nature of the minerals and the aridity of the climate.

Fig. 2 Summary of the various lateritic solums according to the bedrock (constituted from Leprun's observations, 1979).

Fig. 3 (a) Pedoclimatic zoning observed in natural laterites and (b) numerical simulations of the stability domains of the main iron and aluminum oxide minerals as a function of climatic variables: humidity (i.e., water activity) and temperature. From Trolard F (1997) *Les "oxydes" de fer des latérites et des sols hydromorphes—géochimie, minéralogie et modélisations thermodynamiques*. Agrégation de l'Enseignement Supérieur, Université Catholique de Louvain (Belgium), 283 pp.

The position of these domains of stability can be modified depending on the state of division of the iron oxides. The influence of the state of division of the minerals is a very sensitive phenomenon, more specifically, in the case of small crystals because a small variation in size leads to significant differences in the stability of the minerals (see also below). Thus, an increase in grain size causes a decrease in the value of the solubility product, and therefore an increase in the stability of the mineral concerned (Trolard, 1988). Thus, increasing the size of the aluminous hematite particles, while keeping that of the goethite constant, leads to a progression of the hematite domains associated with the Al-goethite or boehmite toward increasing water activities.

Azonal soils: Example of hydromorphic soils

Some soils present characteristics, which are independent of climate and the substratum; this is the case for hydromorphic soils. They develop under particular conditions: oxidation–reduction reactions that produce specific features, which are easily recognizable in soils.

Typology of hydromorphic soils

A soil is said to be hydromorphic when it bears characteristics that are attributable to an excess of water. However, several conditions concerning the water regime and the biogeochemical properties of the environment must be fulfilled simultaneously (Table 1). These are: (1) an excess of water, (2) restriction of oxygen sources, (3) presence of metabolizable substrates, (4) at least temporarily

Table 1 Summary of relationships between processes and soil properties.

Processes	Soil properties
Water saturation	Occupation of pore spaces
Waterlogging	High water residence time
Anaerobiosis	As a result of oxygen restriction, the microflora uses other electron acceptors
Oxido-reduction	Electron transfer between donors and acceptors
Hydromorphy	Occurrence of morphological features attributable to excess water

thermal conditions favorable to microbial activity, (5) the presence of chemical elements likely to change the oxidation–reduction state and to record these changes more or less reversibly, called geochemical markers.

In landscapes, seasonally waterlogged soils are often located in areas with low or zero slope where water flows converge toward local depressions (Fig. 4). These areas are observed both on plateaus and in valleys. Whether Stagnosols (Soil Survey Staff, 1999), located on the plateaus or Gleysols observed in the valleys, they are also called topomorphic hydromorphic soils. This is suggested by the coincidence on the map of these soil types with that of the Kirkby index that links the morphometric index to the probability of soil water saturation (Mérot and Bruneau, 1993). In other cases, hydromorphic soils are observed on the slopes (Fig. 4) in association with the lithological discontinuities. Stagnosols are also often called hydromorphic lithomorph soils (Bourri  et al., 1994). In a third situation, hydromorphy is induced by the soil processes themselves, due to changes in the nature and or organization of the constituents drastically modifying the permeability of the soil. They are observed both in Stagnosols and Gleysols and are called automorphic hydromorphic soils (Bourri  et al., 1994).

An example of a well-developed hydromorphic soil is given Fig. 5. The solum presents from top to bottom, an organo–mineral horizon, a bleached horizon where the iron has migrated then an essentially mineral mottled horizon, marked by more or less diffuse precipitation of iron oxides. Such precipitates can become concretions and crusts where the water table fluctuates. Finally, a blue-green horizon, whose color turns to ochre when the soils are open to the outer atmosphere. This color has often been ascribed to the occurrence, in moderately reduced waterlogged soils, of mixed Fe(II)–Fe(III) compounds with the likely structure of green rust (GR) and of Fe^{2+} in the soil solution. This assumption was formulated in the 1960s and has been widely discussed in the literature. This characteristic blue-green color has consequently been used in all soil classifications since the 1960s and adopted in the World Reference Database (WRB) (IUSS—Working Group, WRB, 2022) as the universal criterion for the recognition of oximorphic or redoximorphic features, used to characterize gleyic properties, reducing conditions and stagnic properties.

Iron as the main biogeochemical marker of hydromorphic soils

Among those elements for which the oxidation state can change under present Earth surface conditions, iron is the most abundant, and the switching between di- and tri-valent redox states of iron initiates several significant geochemical reactions. Moreover, the large difference in mobility between Fe^{2+} , soluble, and Fe^{3+} , insoluble (except at very acidic pH) induces segregations of iron in the horizons and or in soil sequences. These differences are ordered in the landscape and are considered responsible for processes that produce concretions (see ref. included in Trolard and Bourri , 2008).

In hydromorphic soils, iron is mobile, sometimes in significant proportions following seasonal dynamics. These dynamics can be of two types: (i) the first is linked to the succession of processes of waterlogging, reduction then aeration, oxidation, classically observed in the neighborhood where the water table fluctuates and (ii) the second is observed when the mobility of the iron is controlled by the degree of water oxygenation, linked to the rapid infiltration of rainwater in a permanently saturated system. These dynamics, which essentially concern Fe(II) in water, condition the mineralogy of iron oxides that are observed in soils. Thus, during

**Fig. 4** Typology of hydromorphic soils.

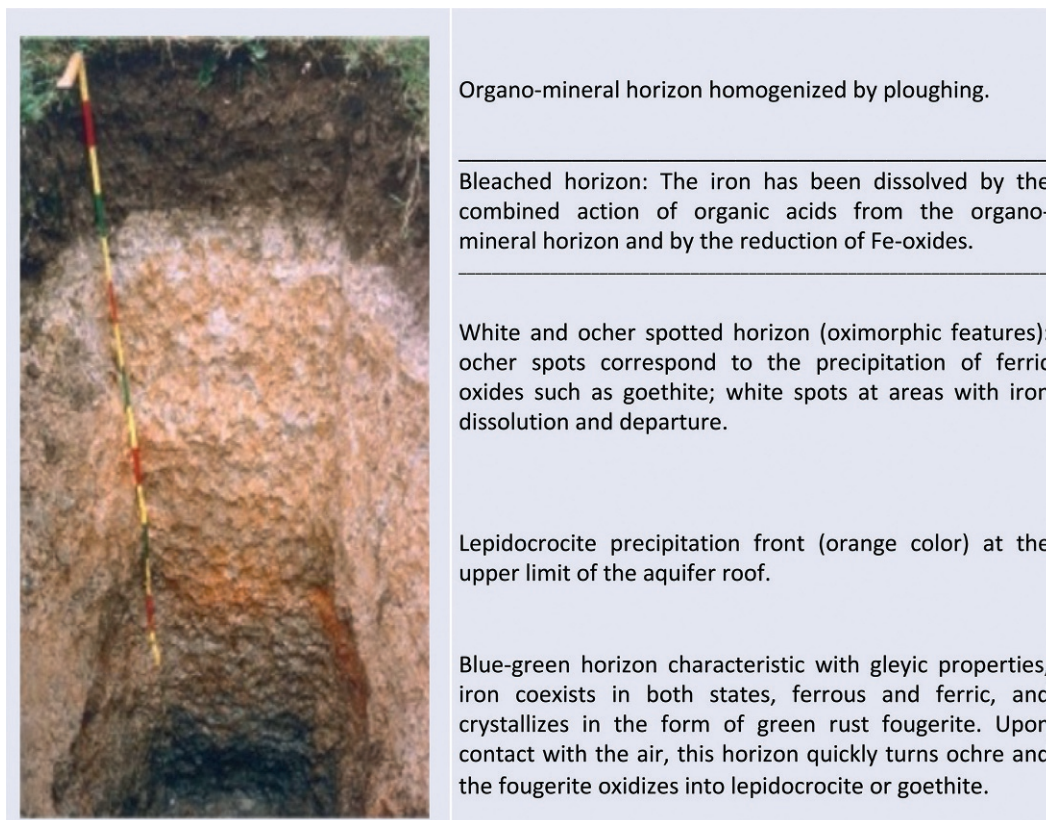

Fig. 5 An example of a hydromorphic soil developed in the granitic area of Brittany, France. Modified from Trolard F, Bourrié G (2008) Chapter 5: Geochemistry of green rusts and fougerite: A reevaluation of Fe cycle in soils. *Advances in Agronomy* 99: 227–289. [https://doi.org/10.1016/S00652113\(08\)00405-7](https://doi.org/10.1016/S00652113(08)00405-7).

the period of oxidation, the dominant Fe oxides are lepidocrocite, in environments where the water is poor in other soluble elements, and ferrihydrite and goethite in other cases. During the period of reduction, if the medium is moderately reduced, green rust, fougerite, becomes the main mineral (soil becomes a blue-green color), and if the medium becomes strongly reducing Fe-sulfides (black color) precipitate.

Pathways of iron mineral formation

Study of the formation of iron oxide pathways in natural environments has been a widely developed topic in the literature for more than a century. It has also been supported by numerous laboratory studies because iron oxides are compounds that can be easily synthesized at ambient temperature and pressure, which establishes knowledge of their structure, their thermodynamic stability and reactivity. This topic has experienced renewed interest over the past 15 years, in particular through research on iron oxides in nanosized particle form.

Natural forms of iron oxides

Iron oxides exist in a bewildering variety of polymorphs (Cornell and Schwertmann, 2003) and the general term “oxide” refers to metal hydroxides, oxyhydroxides and hydroxides. Anhydrous oxides include hematite, α -Fe₂O₃ and maghemite, γ -Fe₂O₃, which both contain only ferric iron and, magnetite, Fe₃O₄, which contains both ferric and ferrous iron. Maghemite and magnetite, with their spinel structure, can form a continuous solid solution. The main oxyhydroxides observed in soils and surface environments include goethite, α -FeOOH, lepidocrocite, γ -FeOOH, and akaganeite, δ -FeOOH. More hydrated forms such as ferrihydrite, nominally Fe(OH)₃, but whose proposed structures are also approximatively Fe₅HO_{8.4} H₂O, better recast as FeOOH.0.4 H₂O, and schwertmannite, ideally Fe₈O₈(OH, SO₄)₁₂₋₁₃ · 10–12 H₂O, has even more variable water content. Hydrated phases containing both ferrous and ferric iron include green rust fougerite, $[(Fe^{II},Mg)_{1-x}Fe_x^{III}(OH)_2]^{+x}[x/n A^{-n}, mH_2O]^x$, with a layered structure where A is the interlayer anion, n is its valency and $1/4 \leq x \leq 1/3$ (Trolard et al., 2007). The octahedron is the basic structural unit for all Fe oxides. Each Fe atom is surrounded by six oxygens either both O₂²⁻ and OH⁻ ions or only OH⁻ in the case of fougerite. In this latter mineral, the presence of Fe(III) gives a positive charge to the hydroxide sheet, which is compensated by interlayer anions with numerous possible types (Trolard et al., 2022). The various Fe oxides differ primarily in their ratios of O/O + OH and Fe^{III}/Fe_{total} (Fig. 6), the octahedra arrangements and how they are linked.

Fig. 6 Pathways between the major iron oxides. Modified from Trolard F, Bourrié G (2008) Chapter 5: Geochemistry of green rusts and fougerite: A reevaluation of Fe cycle in soils. *Advances in Agronomy* 99: 227–289. [https://doi.org/10.1016/S00652113\(08\)00405-7](https://doi.org/10.1016/S00652113(08)00405-7).

The master variables that control the stability of iron oxides

The three main variables that control the reactions in the soil are: (i) the hydrogen potential or pH, (ii) the electron potential or pe and (iii) the size of the iron minerals. The first two variables can be measured only in aqueous medium; our comment below applies only to chemistry in the domain of water stability. The third variable concerns the solid phase when the size of the polymorphs has a significant impact on the stability and reactivity of iron oxides.

In aqueous media: The hydrogen potential, pH and the electron potential, pe

The hydrogen potential or pH is related to the activity of the hydronium ions H⁺ in solution by the relationship:

$$\text{pH} = -\log[\text{H}^+], \quad (1)$$

where [H⁺] defines the activity of hydrated protons. The pH is determined by the relative abundances of acids (proton donors) and bases (proton acceptors), according to the Henderson–Hasselbalch equation:

$$\text{pH} = \text{pK}_a + \log \left(\frac{[\text{Don}_\text{H}]}{[\text{Acc}_\text{H}]} \right), \quad (2)$$

where pK_a is the decimal cologarithm of the acidity constant of the acid–base couple, [Don_H] is the activity of the proton donor and [Acc_H] is the activity of the proton acceptor of the acid–base couple considered.

In the neutral to moderately alkaline or acid pH range, between 5 and 8, iron oxides are very stable and very sparingly soluble. At very acidic pH, below 3, the Fe³⁺ ions can be free in solution and the iron oxides dissolved. At the other extreme, at very alkaline pH values above 10, iron oxides can be destabilized by releasing Fe(OH)[−] or Fe(OH)₂[−] anions into solution.

The electron potential, pe is similarly defined by:

$$\text{pe} = -\log[\text{e}^-], \quad (3)$$

where [e[−]] is the electron activity. The pe is determined by the relative abundances of electron donors and electron acceptors, according the following equation:

$$\text{pe} = \text{pe}^0 + \log \left(\frac{[\text{Don}_\text{e}]}{[\text{Acc}_\text{e}]} \right), \quad (4)$$

where pe⁰ is the value of pe under standard conditions ($P = 10^5 \text{ Pa}$, $T = 298.15 \text{ K}$), [Don_e] is the activity of the electron donor and [Acc_e] is the activity of the electron acceptor of the redox-couple considered.

The pe is related to the oxidation–reduction potential, E_h, by the relationship:

$$\text{pe} = nF E_\text{h} / \ln(10) RT, \quad (5)$$

where n is the number of electrons involved in the half-reactions, F is the Faraday constant ($=96,485 \text{ C mol}^{-1}$), R the ideal gas constant ($8.3144 \text{ J mol}^{-1} \cdot \text{K}^{-1}$) and T the absolute temperature (K).

However, there are fundamental differences between pH and pe in water because water is a protolytic solvent on the one hand and an insulator on the other. The hydrated protons, of which H_3O^+ is the first, are constituents of the solvent and when there is a reaction equilibrium is established almost instantaneously (a few pico-seconds to a few seconds) with the acids and bases. This is also true for the hydroxylated surfaces of many solid soil compounds, including iron oxides. Therefore, even in the absence of strong acids or bases, pH is a well-defined variable, directly measurable in the soil solution with a pH electrode, for establishing the intensity of proton transfer reactions.

On the contrary, the redox equilibria are referenced against the normal hydrogen electrode, but the electron cannot flow freely in the aqueous medium because water is an insulator. Therefore, the pe of an aqueous solution is not related to a free chemical entity, but describes the tendency to accept or donate electrons from reactive compounds (Schüring et al., 2000). It is therefore necessary that an electron donor and an electron acceptor become close neighbors for a reaction to proceed and these reactions are relatively slow (a few seconds to several minutes or even an hour). Thus, measurement by a redox electrode, possible only in an aqueous medium, provides information on the redox state of the soil only through measurement of the ratio of the activities of certain electroactive redox couples such as $\text{Fe}^{2+}/\text{Fe}^{3+}$, $\text{H}_2/\text{H}_2\text{O}$ or $\text{H}_2\text{S}/\text{S}^0$. Another difficulty lies in the fact that in soils, some oxidation–reduction reactions are homogeneous in aqueous solution, but many others are heterogeneous and involve both solids and the solution. Thus Sposito (1981) defined a critical electron potential, $\text{pe}_{\text{critical}}$, computed at a given pH and for a given ratio of the activities of Don_e and Acc_e . Accordingly, for homogeneous reactions, the $[\text{Don}_e]/[\text{Acc}_e]$ ratio is taken conventionally to be 10^6 . For heterogeneous reactions, where the oxidized species is a solid and dissolves during reduction, $[\text{Don}_e]$ is taken as 10^{-7} , with the assumption that the solid phase is pure and its activity $[\text{Acc}_e]$ is equal to 1. For pe smaller than the “critical” value, the reduction reaction is considered as quasi-complete. In the particular case of iron, it is then possible to observe that over the entire water stability domain, there are redox couples that can control the dynamics of iron at the solid–solution interface (Fig. 7).

In the solid phase: Size of iron mineral

Iron oxides in soils are commonly fine-grained and poorly crystalline. Thermodynamically, the competition between surface enthalpy and the energetics of phase transformation leads to the general conclusion that polymorphs, which are metastable as micrometer-sized or larger crystals can often be stabilized at the nanoscale. This question is important because each material has unique physical properties, chemical reactivity and bioavailability. Furthermore, physical and chemical properties change with particle size and degree of hydration (Navrotsky et al., 2008). Advances in nanosciences, new structural spectroscopies and

Fig. 7 Scale of “critical” values of E_h for major Fe redox couples, computed at pH = 7 and valid for $[\text{HCO}_3^-] = 10^{-3} \text{ M}$; phen, phenanthroline; sal, salicylate; porph, porphyrine and GR, green rust. From Trolard F, Bourrié G (2008) Chapter 5: Geochemistry of green rusts and fougérite: A reevaluation of Fe cycle in soils. *Advances in Agronomy* 99: 227–289. [https://doi.org/10.1016/S00652113\(08\)00405-7](https://doi.org/10.1016/S00652113(08)00405-7).

thermodynamic approaches are now enabling knowledge of structural details, thermodynamics and reactivity, particularly of nano-scaled iron oxides, to be acquired.

The structure of nanoparticles often varies as a function of their size and the surrounding medium. For example, hematite nanoparticles may vary in structure showing tetrahedral defects near the surface with a maghemite-like structure. As another example, it has been shown that the surface regions in poorly crystalline lepidocrocite are sufficiently different from the bulk for their Mössbauer signals to be distinguished and referenced to a lepidocrocite–hematite mixture (De Grave et al., 1986); or when the crystal size of akaganeite becomes sufficiently small, akaganeite may contain goethite-like structure possibly related to the collapse of exposed tunnels (Deore, 2007). The structure of ferrihydrite is still in debate: is it a single phase with iron both octahedrally and tetrahedrally coordinated, or a mixture of phases with variable structure and crystallinity (Carabello et al., 2022)? Finally, GR and fougérite with a layered double hydroxide structure crystallize mainly in the form of nanoparticles due to the relative stability of the hydroxide sheet compared to other polymorphs of iron oxides. Moreover, its anionic clay structure gives unique properties to GRs and fougérite that allows them to accommodate or interact with more than 30 chemical elements and molecules, including organic ones. Their sheet structure also represents a configuration conducive to the realization of certain oxidation–reduction reactions (see references included in Trolard et al., 2022).

Small particles are expected to have higher enthalpies and free energies than large crystals because of a positive surface energy. In contact with water, the nanoparticles hold on to their water tenaciously. As metastability of the coarse phase increases, its surface enthalpy decreases. The increasing metastability of the bulk polymorph leads to crossovers in enthalpy (and also in free energy) of polymorphs at the nanoscale. With thermodynamic data (Table 2), values of surface enthalpies also correlate with the heat of surface hydration and the fraction of strongly bound water (Navrotsky et al., 2008).

For example, the most stable iron oxide, hematite, absorbs water the most strongly; the water fraction that is strongly bound on goethite is 60%, 40% for akaganeite and lepidocrocite. Thus, maghemite becomes stable with respect to hematite and there are complex crossovers for the FeOOH polymorphs.

Surface properties of iron “oxides”

“Oxides” (s.l. including oxides, hydroxides and oxyhydroxides) can contribute, under certain conditions, to the characteristic surface charge of a material. Their hydroxylated surfaces take part in the reactions of dissociation or association of protons. The surface potential is thus governed by the adsorption of H^+ and OH^- ions, called potential determining ions (PDI). The properties of such minerals are different from those of clay minerals. In the case of clays, the surface properties are governed by the surface charge due to isomorphic substitutions in the layers by ions having a valence generally lower than those of the replaced ions, thus creating a charge imbalance. The surface charge is thus fixed by the rate of substitution in the mineral, independently of the pH and ionic strength of the electrolyte (Jolivet, 2015).

In the case of iron oxides, iron does not participate directly in the surface charge (Fig. 8). Surface charge is variable and is determined by the chemical composition of the solution with which the oxide equilibrates. Depending on the pH, iron oxides can trap either A^- anions, or A^+ cations and also neutral species.

Table 2 Thermodynamic data for some iron oxides.

Oxide	ΔH_f° (kJ.M ⁻¹)	S° (J.M ⁻¹ .K ⁻¹)	ΔS° (J.M ⁻¹ .K ⁻¹)	ΔG_f° (kJ.M ⁻¹)	ΔH_s^h (J.m ⁻²)	ΔH_s (J.m ⁻²)
Hematite, α -Fe ₂ O ₃	-826.2 ± 1.3	87.4 ± 0.2	-274.5 ± 0.3	-744.4 ± 1.3	0.75 ± 0.16	1.90 ± 0.3
Maghemite, γ -Fe ₂ O ₃	-811.6 ± 2.2	93.0 ± 0.2	-268.9 ± 0.3	-731.4 ± 2.0	0.57 ± 0.10	0.71 ± 0.13
Goethite, α -FeOOH	-561.5 ± 1.5	59.7 ± 0.2	-237.9 ± 0.2	-490.6 ± 1.5	0.60 ± 0.10	0.91 ± 0.09
Lepidocrocite, γ -FeOOH	-552.0 ± 1.6	65.1 ± 0.2	-232.5 ± 0.2	-482.7 ± 3.1	0.40 ± 0.16	0.62 ± 0.14
Akaganeite, β -FeOOH	-554.7 ± 1.9	53.8 ± 3.3	-246.2 ± 3.3	-481.7 ± 1.9	0.34 ± 0.04	0.44 ± 0.04

Enthalpies of formation (ΔH_f°) and Gibbs free energies of formation (ΔG_f°) are for conditions of 298.15 K and 1 bar. Surface enthalpies are given for hydrated (ΔH_s^h) surfaces.

From Navrotsky A, Mazeina L, and Majzlan J (2008) Size-driven structural and thermodynamic complexity in iron oxides. *Science* 319(5870): 1635–1638. <https://doi.org/10.1126/science.1148614>.

Fig. 8 Schematic representation of the surface charge of iron “oxides.” H^+ and OH^- are the potential determining ions (PDI).

At acidic pH, iron oxides are positively charged and therefore have an appreciable anion exchange capacity, when present in sufficient quantity in soils. In an alkaline medium, the capacity of iron oxides to absorb OH^- gives them, when they are in sufficient quantity, a buffering power, which can be significant.

Organic matter is negatively charged over a wide range of pH, giving soils a negative net surface charge in the superficial horizons. However, if the amounts of soil organic matter have been greatly reduced by agricultural practices or deforestation, for example, the positive surface charge of iron oxides can take over. In this situation, the soil has a low capacity for the retention of cationic nutrients (e.g., Ca, K, Na, . . .), which are then easily leached. This is an important problem in tropical and equatorial zones where soils develop in a hot climate marked by heavy rainfall. One of the methods proposed to increase the cation exchange capacity is amendment with anionic silicates which, by adsorbing preferentially on the iron oxides, relatively increase the net negative surface charge of the soil by reducing the positive charge of the “oxide.”

Evidence of in situ dynamics of iron minerals

Fast mineralogical transformations can be observed in situ at well-defined points in a soil, at different times and depths by a portable Mössbauer spectrometer. Observations were made in hydromorphic soils of Fougères's forest in Brittany (France). During alternating aerobic and anaerobic conditions, the soil color changes from ochre to blue in the horizon deeper than 70 cm. Fougérite is the almost exclusive iron mineral of the system, except during the summer when lepidocrocite can occur. Seasonal variations in the $\text{Fe(III)}/\text{Fe}_{\text{total}}$ ratio at a given point and depth are observed; the variations remain in the interval $[1/3; 2/3]$ of the stability domain of fougérite. The more ferric minerals are observed in the upper oximorphic soils, whereas the more ferrous forms are present in the lower reductimorphic horizons. At a given depth, rapid temporal variations of this ratio are correlated with fluctuation of the water table, causing alternating aerobic and anaerobic conditions. Monitoring by Mössbauer spectrometry in situ, at a given depth, also highlighted the crystallization of fougérite in less than a week in sufficient concentrations for a signal to be recorded and compatible with the Fe^{2+} contents and the volume of soil solution available at this location (Féder et al., 2005). This demonstrates that fast and reversible mineralogical transformations of iron oxides can exist in these soils. Fast geochemical phenomena in soils are thus not restricted to ion exchange or precipitation or dissolution of salts, as classically considered.

Another way to show that iron oxide mineralogy can be a good indicator of soil evolution is by making measurements of iron isotopes. Iron isotopes are geochemically robust and retain their environmental signature even under extreme metamorphic conditions, which makes them a useful tool in deciphering the biogeochemical history of highly deformed and metamorphosed rocks (Peacock et al., 2016). Iron has four naturally occurring stable isotopes ^{54}Fe (5.84%), ^{56}Fe (91.7%), ^{57}Fe (2.12%) and ^{58}Fe (0.28%), where stable isotope data are commonly reported as $^{56}\text{Fe}/^{54}\text{Fe}$. In soils, metabolically processed Fe may also retain a “vital effect” due to the redox related changes that control Fe isotope fractionation during iron mineral transformations. Thus, a soil that has undergone or has been subjected to in its history alternations of anaerobiosis–aerobiosis processes resulting in the reduction or the oxidation of iron will show a distribution of iron isotopes at the level of the reaction fronts with:

- an enrichment in heavy isotopes (i.e., ^{56}Fe) in the solid fraction, which undergoes dissolution;
- an enrichment in light isotopes (i.e., ^{54}Fe) in the solid fraction, which precipitates from the Fe(II) of the soil solution.

In an upstream–downstream soil sequence with a hydromorphic front, the $\delta^{56}\text{Fe}$ signature will tend to be high in the upstream part of the sequence and in the superficial horizons and lower in the downstream part of the sequence and in the deeper horizons.

Influence of Fe on landscape evolution

Iron accumulates as Fe(III) oxides, first because most other elements are more mobile, this is a relative accumulation; second, because under reducing conditions Fe(II) is as soluble as Mg(II) . At short distances, in lower parts of the landscape, it precipitates; this is absolute accumulation. Ferricretes form in both cases. As ferricretes are more resistant to erosion, this leads to the formation of relief where former deep horizons or former lowland formations are now present at high elevations, such as in Burkina Faso (Fig. 9).

These high-level terraces are the relics of paleosurfaces that have undergone a long duration weathering of different bedrocks: gabbros, micascists, granites, under a rainforest. They are thus indicators of changes in climate. However, in some other cases, as in NW Hoggar (Mouydir) ferricretes are specifically located on pyrite-rich schists either in alluvial fans or directly on rock outcrops at mid slope positions. In this case, Fe mobility is due to sulfide oxidation into sulfuric acid that results in a very acidic pH (ca. 2). Iron mobility is due, therefore, to local conditions and these ferricretes are not indicators of a past humid paleoclimate.

The Fe(III) oxides appear as nanoparticles that are positively charged in acid conditions, as their pH of zero point of charge is large. These particles are linked with clay minerals, and this gives rise to stable aggregates, and favorable physical properties (large porosity and hydraulic conductivity), typical of ferrallitic and fersiallitic topsoils. These soils typically occur on plateaus. Hydromorphic conditions may develop in depressions at the centers of these plateaus. This results in Fe reduction and destruction of the links between clay minerals and Fe oxides. Soil structure collapses, porosity decreases and also hydraulic conductivity. This, in turn, results in poor drainage and a further decrease of redox potential. Progressively, hydromorphic features extend from the center of the plateau to the entire plateau, with soil color changes (transformation from red soils to beige soils) and a geomorphological transformation of slopes, as observed in West Africa (Chauvel and Pedro, 1978) (Fig. 10).

Cahiers Orstom, série Pédologie, XVI, 3: 231–249.

Interaction iron minerals—Living organisms

It is hard to find a biological process or environment in which iron do not participate. From the Earth's surface to the deep oceans, from pigeon brains to magnetotactic bacteria, anhydrous and hydrated iron oxides are ubiquitous. Iron oxides and oxyhydroxides in rocks and soils, and products of bacterial processes are also an essential source of nutrients for life. Iron is present in all electron transfer complexes, photosystems PSI and PSII, cytochrome *b*/*f*6 complex and ferredoxins. Respiration and photosynthesis rely on

Fe(II)-Fe(III) electron transfer. The role of Fe is also implied in the biogenesis of cofactors, such as heme (iron protoporphyrin XI), a tetrapyrrole cofactor of hemoglobin, and iron–sulfur clusters. Iron deficiency results in chlorosis in plants, because of the lack of chlorophyll synthesis, but this is modulated by P deficiency through complex regulations, which indicate that signals are exchanged between chloroplasts and the cell nucleus (Nam et al., 2021).

The biological importance of iron is a result of its electronic structure, which can reverse changes in oxidation state over a wide range of redox potentials (see Fig. 7). The ease of reversibility of the $\text{Fe}^{2+}/\text{Fe}^{3+}$ couple makes iron a cofactor that is frequently incorporated into protein complexes to catalyze oxidation–reduction reactions. Iron is thus an essential element present in all biological tissues and in all cellular compartments. Iron proteins have essential functions in plant metabolism such as photosynthesis, respiration, DNA synthesis, nitrogen and sulfur metabolism, etc. When incorporated into proteins, iron can be coordinated in different ways: either it is linked to sulfur atoms (iron–sulfur center), or it is linked to nitrogen atoms in the form of heme or directly linked to amino acids.

Key role of siderophores

In general, the availability of iron in the soil solution for the nutrition of living organisms is low or even very low, far below that required for optimal growth: 10^{-5} to 10^{-7} M for microbes and 10^{-4} to 10^{-9} M for plants (Robin et al., 2008). In the soil, iron is mainly present in the form of ferric oxides and oxyhydroxides, which are very stable and poorly soluble at circumneutral pH. In an aerobic aqueous solution, the concentration of free ferric iron (Fe^{3+}) is often less than 10^{-10} M. Many bacteria and fungi, but also the plants, particularly in iron poor soils, get around this impasse by excreting low molecular weight, Fe(III)-specific ligands known as siderophores (from Greek: “iron carrier”). In soils, siderophores or their breakdown products can be so abundant that they dominate ferric iron components. Siderophores have several properties that make them ideal Fe(III) chelators. They usually form a stable, hexadentate, octahedral complex preferentially with Fe^{3+} compared to other metal ions in soil, although they have fewer than six donor atoms. They can also coordinate with water. The most effective siderophores are those that have three bidentate ligands per molecule, forming a hexadentate complex around the central Fe^{3+} cation resulting in a smaller entropic change than that caused by chelating a single ferric ion with separate ligands. The Fe^{3+} is a strong Lewis acid, preferring to coordinate with strong Lewis bases such as anionic or neutral oxygen atoms.

The major groups of siderophores include the catecholates (phenolates), hydroxamates and carboxylates (e.g., derived from citric acid, which can also act directly as a siderophore). They form especially strong 1:1 surface complexes, and their association constant for Fe(III) can be several times higher than common soil organic acids, e.g., oxalic acid. This important property maintains ferric iron in a soluble form that minimizes its loss from the aqueous environment by precipitation of ferric solid oxide and oxyhydroxide.

The wide diversity of siderophores biosynthesized by microorganisms and plants seems to have two objectives:

- produce structurally different siderophores, which cannot be fixed by other microbes' or plants' specific active transport systems, or in the case of pathogens cannot be deactivated by the host organism;
- by a specific signature ensures an exclusive access to a given source of ferric iron-containing mineral.

Pathways for iron in the rhizosphere—Plant system

In the rhizosphere, in particular, the volume of soil surrounding roots where microorganisms are influenced by the living roots the competition for iron is very high, and the organisms have evolved active uptake strategies to increase the availability of iron (Fig. 11) by:

- acidification through proton extrusion (proton pump), organic acid secretions and an increase of pCO_2 by respiration;
- chelation through secretion of siderophores, whose biosynthesis is tightly controlled by available iron concentrations and;
- reduction through secretion of molecules with reducing properties or through the expression of a membrane-bound reductase activity.

These organic and inorganic substances, named rhizodeposits, exert a direct influence on soilborne microorganisms including antagonistic and phytopathogenic populations. Rhizodeposition affects soil microorganisms leading to (i) an increase in their density, biomass and activity; and (ii) variation and diversity of their populations. Energetic metabolism of heterotrophic microorganism is based on electron donors (organic compounds) and electron acceptors (oxygen, nitrogen oxidized species, e.g., nitrate, or ferric oxides). Microbial siderophores can also trigger defense responses in the host plant and promote plant iron nutrition.

Strategies of iron up-take by organisms

In the soil, iron is mainly found in the form of insoluble ferric iron oxide or oxy-hydroxides. Before absorbing iron from the soil, plants and soil organisms must solubilize it. There are two iron uptake strategies: (i) strategy I is found in all dicots and non-grass monocots, and (ii) strategy II in other organisms, such as grass monocots, bacteria and fungi (Robe, 2021).

(a)

(b)

Fig. 11 Schematic representation of (a) iron-mediated interactions between plants and microbes promoting plant health and iron nutrition (b) the two strategies for iron uptake by organisms. Panel (a): Modified from Robin A, Vansuyt G, Hinsinger P, Meyer JM, Briat JF, Lemanceau P (2008) Chapter 4: Iron dynamics in the rhizosphere: Consequences for plant health and nutrition. *Advances in Agronomy* 99: 183–213. [https://doi.org/10.1016/S00652113\(08\)00404-5](https://doi.org/10.1016/S00652113(08)00404-5). Panel (b): Modified from Robe K (2021) Localisation, dynamique et rôle des coumarines dans la nutrition en fer chez *Arabidopsis thaliana*, Thèse de Doctorat, Montpellier SupAgro, Université de Montpellier, 407 pp.

Strategy I consists of removing iron from the soil by acidifying the external environment and thus solubilizing the iron so that it can be transported into the cell. Excretion of protons by H^+ -ATPases (AHA) is quite rapid. Roots can lower soil pH to around 3 within hours, increasing iron solubility by a factor of 1000.

In a situation of iron deficiency, the plant can emit phytosiderophores (e.g., coumarins, flavins, etc.) capable of chelating the Fe^{3+} released by acidification. The iron Fe^{3+} is subsequently reduced to ferrous iron (Fe^{2+}) by membrane reductases FRO (ferric reductase oxidase). Finally, ferrous iron is transported into the root by membrane transporters with a high affinity for Fe^{2+} , and IRT (iron regulated transporter) located on the plasma membrane of the root epidermis (Fig. 11b).

Recent work has shown that IRT, FRO and AHA interact physically at the plasma membrane, that their physical proximity ensures optimal iron acquisition and that their activities are proportional to the availability of iron in the rhizosphere, i.e., the more that iron from the soil is scarce, the higher are their activities.

Strategy II does not require the reduction of Fe^{3+} to Fe^{2+} (Fig. 11b). In this case the organisms secrete siderophores capable of dissolving iron oxides and oxyhydroxides and of directly chelating the released Fe^{3+} . The production of siderophores is all the more important because iron is rare in the living environment of the organisms. Among the phytosiderophores, mugineic acids (MA) are produced by plants and are secreted by the transporter TOM ("transporter of mugineic" acid family phytosiderophore). The ferric iron complex thus chelated is then assimilated by the plant using the YS/YSL transporter (Yellow Stripe/Yellow Stripe Like).

Among plants, rice (*Oryza sativa* L.) has both Strategy I and Strategy II iron acquisition components. Although rice mainly uses the Strategy II pathway, an Fe^{2+} transporter was identified and a slight ferric reductase activity was measured. These specificities can be explained by the fact that rice often grows in anoxic flooded environment where Fe^{2+} can be present; the presence of an Fe^{2+} -transporter under these conditions is therefore an advantage for the plant.

Iron is an essential nutrient for all living organisms but it can lead to cytotoxicity when present in excess. In plants, classic symptoms of Fe toxicity are leaf discoloration (bronzing) and a stunted root system.

Excessive Fe generates oxidative stress inside two important cell compartments, i.e., mitochondria and plastids, in organisms including plants. Surplus free Fe produces hydroxyl radicals through the Fenton reaction, displays enhanced production of ROS and stimulation of oxidative stress-detoxifying enzymes. The unusually elevated Fe content and production of ROS in mitochondria lead to increased production of NO in frataxin-deficient plants. This enriched production of NO has been observed to be a crucial feature to reduce high levels of oxidative damage in the root cells of plants. Interestingly, NO accumulation may, perhaps, protect plants from oxidative stress either by direct scavenging of O_2^- or indirectly by NO-induced expression of ferritin genes (AtFer1 and AtFer4). Thus, NO certainly plays an essential role in reducing the levels of free Fe within the plant cell organelles; further, it maintains a check on the ROS production with subsequent protection of plants from oxidative stress and apoptosis (see references included in Zaid et al., 2020).

Iron toxicity often occurs in rice crops in the context of submerged paddy fields where redox potential decreases, leading to increases in the concentration of ferrous ions, disrupting cell homeostasis and impairing leaf and root growth and yield.

Conclusion

Iron in the soil is an essential chemical element that contributes both to the structure of soils and to their organization in landscapes. It plays an essential role as a trace element and nutrient for all organisms that feed on soil constituents. It is virtually insoluble in the ferric state at pH close to neutral, and it is expressed in the mineral form of oxides, hydroxides and oxy-hydroxides. Iron can also become as soluble as an alkaline or alkaline-earth cation in its reduced form Fe^{2+} , when the milieu becomes moderately reducing. This duality of insoluble/soluble and oxidized/reduced redox state of iron is a cornerstone of soil formation both zonally and azonally in all surficial Earth formations. These properties are also essential in the mechanisms put in place by organisms to obtain the quantity of iron they need to live from soils where a priori the bioavailability of iron is low.

Abstract

Sulfur (S) plays an irreplaceable role in the biological functions of plants. Selenium (Se) is an essential micronutrient for humans and a beneficial element for plant growth. Because S and Se have similar chemical properties, exploring their behavior and interactions in soil are of great importance to clarify the S and Se supply potential of soil and guide possible Se biofortification in agricultural production. The physicochemical properties, sources, content, speciation distribution, chemical transformation, and bioavailability of S and Se in soil are summarized in this chapter to show their similarities and differences and corresponding mechanisms in soil.

Key points

- Summarize the physicochemical properties, sources, content, speciation distribution, chemical transformation, and bioavailability of S and Se in soil.
- Clarify the interaction mechanisms between Se and S and the regulatory measures of their bioavailability in soil.

Introduction

Sulfur (S) and selenium (Se) are essential nutrients for humans and animals. Although Se is not necessarily an essential nutrient for plant growth like S, plants are the main source of Se intake for humans and animals. Soil is an important pathway for Se and S entry into the food chain through plants. Since Se and S belong to the same group in the periodic table of elements, they have similar chemical properties. Therefore, understanding the similarities and differences in the chemical properties and behavior of S and Se in soil is of great significance to regulate their bioavailability and promote crop growth.

Table 1 Physicochemical properties of S and Se.

Element properties	S	Se
Periodic position	Group VIA, Period 3	Group VIA, Period 4
Atomic number	16	34
Atomic weight	32.065	78.96
Atomic radius	102 pm	120 pm
Stable isotopes	³² S, ³³ S, ³⁴ S, ³⁶ S	⁷⁴ Se, ⁷⁶ Se, ⁷⁷ Se, ⁷⁸ Se, ⁸⁰ Se, ⁸² Se
Melting point	385.95 K	494 K
Boiling point	717.75 K	958 K
Oxidation states	-2, 0, +4, +6	-2, -1, 0, +4, +6
Mohs hardness	2	2
Density	2.36 g/cm ³	4.81 g/cm ³
Electronic configuration	[Ne] 3s ² 3p ⁴	[Ar] 3d ¹⁰ 4s ² 4p ⁴
Electronegativity	2.58	2.54
Ionization potential	10.413 eV	9.752 eV
CAS#	7704-34-9	7782-49-2

Sulfur is a non-metallic element with atomic number 16 and CAS (Chemical Abstracts Service) accession number 7704-34-9. It is a group VIA element and lies in the third period of the periodic table of elements. Sulfur is active in nature and has many valence states; it usually exists in the form of sulfide (HS⁻), sulfate (SO₄²⁻), or elemental sulfur (S⁰). In general, S⁰ presents as yellow crystals and has many allotropes, such as rhombic, monoclinic, and elastic sulfur. Moreover, S⁰ is insoluble in water, slightly soluble in ethanol, and easily soluble in carbon disulfide. It is mainly used to produce fertilizer, gunpowder, lubricants, pesticides, and antifungal agents. Sulfur plays an irreplaceable role in the life activities of animals and plants; it is not only a medium-element for plants to synthesize important substances but also a participant in several metabolic processes of plants, such as respiration, protein synthesis, lipid synthesis, and sugar metabolism. However, S is also a chemical pollutant. Acid deposition, the greenhouse effect, and ozone layer depletion, for instance, are all related to S pollution.

Selenium is between arsenic (As) and bromine (Br) in the fourth period and between S and tellurium (Te) in group VIA of the periodic table of elements. The atomic number and mass of Se are 34 and 78.96, respectively, and its electronic configuration is [Ar] 3d¹⁰ 4s² 4p⁴ (Table 1). Elemental Se (Se⁰) is a red or gray powder that is insoluble in water and ethanol, soluble in concentrated sulfuric acid and chloroform, and slightly soluble in carbon disulfide. Although Se is a non-metallic element, it is conductive and, thus, often used as semiconductor and photosensitive material. In nature, Se mainly exists in two forms: inorganic and organic Se. Inorganic Se mainly includes selenate (SeO₄²⁻) and selenite (SeO₃²⁻), while organic Se mainly includes selenomethionine (SeMet), selenocysteine (SeCys) and methyl-SeCys (MeSeCys). As the active center of various selenoenzymes and selenoproteins, Se plays important physiological functions in regulating hormone metabolism in the thyroid gland, antagonizing heavy metals, and maintaining oxidation-reduction homeostasis. Therefore, Se is considered an essential micronutrient for animals and humans, and a beneficial element for plant growth. However, excessive intake of Se also has negative effects on human health, and the range between the necessary (40 µg day⁻¹) and toxic (>400 µg day⁻¹) doses of Se is narrow. Consequently, ensuring that the Se content of crops reaches an appropriate amount to meet human daily needs and avoid Se toxicity is crucial with the Se biofortification of crops.

The chemical properties of Se are very similar to those of S in terms of periodic position, oxidation states, atomic size, electronegativity, and ionization potential (Table 1, Fig. 1). Therefore, selenate can pass through the root cell membrane through SO₄²⁻ transport channels and compete with the latter for crop absorption. Because of defects in biological identification, Se absorbed by plants can replace S in S-containing proteins (e.g., methionine (Met)), thus nonspecifically incorporating it into a Se-containing protein (e.g., SeMet), or specifically incorporating it into selenoprotein as the active site of SeCys, thereby interfering with the normal functions of the protein (B'Hymer and Caruso, 2006). Selenite is mainly absorbed by crops through the transport channels of phosphate (PO₄³⁻) or other ions. The major difference between Se and S is that Se exists in the reduced quadrivalent form, while S exists in the oxidized quadrivalent form. In addition, the acid strength of Se is higher than that of S (i.e., coefficient of acidity [pKa]: hydrogen selenide (H₂Se) > hydrogen sulfide (H₂S)). Therefore, in view of the similarities of the chemical and physical properties of Se and S, understanding their distribution and transformation in soil and exploring the similarities and differences in their environmental chemical behavior in this matrix further are necessary to clarify the S supply potential of soil and guide the biofortification of Se in agricultural production.

Sulfur in the soil

Sulfur sources in soil

The inputs of S into soil include parent material, atmospheric deposition, irrigation water, and fertilization, etc. After the natural weathering of rock or minerals, the main S-containing minerals, such as gypsum, are decomposed by microorganisms in the soil and transformed into SO_4^{2-} . Under the comprehensive action of biology, physics and chemistry, SO_4^{2-} undergoes a series of migration and transformation processes and enters the soil through the absorption and decomposition of plants or runoff and tidal migration. Atmospheric S sources can be divided into natural S sources and anthropogenic S sources. Natural S sources are mainly gaseous S oxides and H_2S emitted from volcanic activities, crustal hydrothermal activities, and processes in waterlogged areas. Anthropogenic sources of S are gases from coal and crude oil combustion. Agricultural irrigation and fertilizer also contain some S to meet the needs of crop growth.

Sulfur contents in soil

Sulfur is the fourteenth most abundant element in the Earth's crust. The total S content in agricultural soil is usually between 0.03 g kg^{-1} and 10 g kg^{-1} , with the average is approximately 0.7 g kg^{-1} (Alloway, 2013). The total S in soil correlates strongly with soil organic C and total N, thereby suggesting that S is an integral part of soil organic matter. The content of S in soil varies with the original content of the soil parent material, changes in the soil formation process, climatic conditions, and land use types. The content of S in magmatic rocks is lower than that in sedimentary rocks, and its content in mineral soils is generally between 0.1 g kg^{-1} and 0.5 g kg^{-1} . In addition, the S content of mineral soils increases with increasing organic matter content. The total S content in subtropical cultivated soil is usually lower than that in temperate soil because of the leaching effect accompanied by strong weathering and lower organic matter content. The content of soil available S varies with the land utilization, which is in the order of paddy field > orchard > upland soil > forest land for these four land use types. Because organic matter accumulates easily in paddy soil and irrigation water can carry considerable amounts of S into soil, the available S in paddy fields is generally higher than that in upland soil. The abundance and deficiency of available S in soil can be divided into four levels: less than 10 mg kg^{-1} which is deficient, $10\text{--}16 \text{ mg kg}^{-1}$ which is potentially deficient, $16\text{--}30 \text{ mg kg}^{-1}$ is medium, and more than 30 mg kg^{-1} is abundant (Liu et al., 1990).

Sulfur speciation in soil

Sulfur in soil mainly exists in different oxidation states, namely, hexavalent (e.g., sulfate, S(VI)), tetravalent (e.g., sulfite, S(IV)), negative bivalent (S(-II)), and nonvalent (S(0)). In soil, S occurs in inorganic and organic forms.

In general, the majority of S in soil is bound to organic molecules, usually accounting for over 60% of the total S; it occurs mainly in soil organic matter (SOM) and animal or plant residues. At present, the specific chemical composition of organic S in soil is not well understood. According to the reduction method of hydroiodic acid (HI) proposed by Johnson and Nishita (1952), organic S can be divided into three forms: carbon-bonded S (C—S), sulfate esters (C—O—S), and unknown organic S (UO—S). Carbon-bonded S is the fraction of organic S bound directly to carbon (C), which can be reduced to H_2S by Raney nickel. This fraction consists of S-containing amino acids, thiols, sulfoxides, sulfinic acids, and sulfonic acid linked to an aromatic nuclei. The C—O—S is relatively stable and leads to lower S availability than C—S for plants. Organic S not directly bound to C, such as sulfonic acid esters, some sulfamic acids, and S-cysteine sulfonic acid, among others, is composed primarily of C—O—S , which is reduced to H_2S by HI (Lucheta and Lambais, 2012). This fraction accounts for 30–70% of the organic S and is an active component of organic S in soil. The C—O—S is easier to convert into inorganic S than C—S , and can be utilized by plants (Blair et al., 1991). The third fraction of organic S, UO—S or residual S, and its availability to plants require further study.

The species of S in soil mainly includes SO_4^{2-} , sulfite (SO_3^{2-}), sulfide (S^{2-}), and S^0 . Sulfur also can be divided into water-soluble, adsorbed, hydrochloric acid-soluble, and zinc-hydrochloric acid-reducing S according to the sequential extraction method. The main existing valence state of water-soluble S in soil is SO_4^{2-} , which mainly exists in soil solution. A small amount of reducing inorganic S, such as H_2S , HS^- , S^{2-} , and S , has also been noted, and the contents of these substances is usually less than 10%. Adsorbed S is retained on the surface of soil colloids by anion exchange adsorption and coordination adsorption (Wilhelm, 2009). Hydrochloric acid-soluble S is precipitated by the combination of calcium carbonate and magnesium carbonate in soil and can be dissolved under acidic conditions. Acid-volatile sulfide, a volatile sulfide that can be decomposed under acidic conditions, is the least common form of inorganic S in soil.

Transformation processes of sulfur in soil

The S pools in soils are dynamically balanced and controlled by complex mechanisms, including the immobilization of inorganic S forms in organic and mineral soil layers; these inorganic forms are usually incorporated into organic matter by covalent bonding. The mobilization of large organic S molecules into smaller ones and mineralization to yield plant-available inorganic S are other mechanisms controlling the S pools in soil.

Mineralization of organic sulfur

The S in the surface layer is mainly organic, but the S absorbed directly by plants from the soil is almost completely inorganic S. Organic S must be converted by biochemical (e.g., hydrolyzation of sulfate esters by different sulfatases) or microbiological (e.g., mineralization of C-bonded S) means to obtain inorganic SO_4^{2-} prior to plant uptake. The mineralization of organic S links organic and inorganic S in the soil and is an important means through which plants obtain available S; this process is also an essential link in the biogeochemical cycle of soil S. Studying the rate of mineralization and capacity of organic S in the soil helps in estimating the S supply capacity and evaluating the potential productivity of the soil.

The mineralization of organic S in soil can be divided into biochemical and biological mineralization. Soil microorganisms and plant roots produce a type of sulfatase when the content of SO_4^{2-} in soil is low. Biochemical mineralization refers to the release of SO_4^{2-} from the C—O—S pool through enzymic hydrolysis (Fitzgerald, 1978). The reaction process is as follows:

Biological mineralization occurs when microorganisms use compounds containing C-bonded S as C sources to provide energy. In this process, S is released as a by-product of the oxidation of C to CO_2 . Under aerobic conditions, organic matter is decomposed by microorganisms and organic S is oxidized into SO_4^{2-} . However, organic S is reduced to H_2S under anaerobic conditions. Many studies have shown that biological mineralization is the main process by which organic S is mineralized in soil, and the amount of mineralization at any time depends on the soil physicochemical properties, such as temperature, humidity, pH, nutrient status, addition of organic or inorganic substances, and plant growth.

Immobilization of inorganic sulfur

Immobilization of inorganic S and mineralization of organic S occur simultaneously in soil. The immobilization of inorganic S is affected by SO_4^{2-} and organic C contents of the soil. Most S is converted into the C—O—S when the content of SO_4^{2-} is high in the soil solution. By contrast, the immobilization of inorganic S is reduced. The extent of immobilization depends on the C:S ratio in the soil. When the C:S ratio is below 200, mineralization of organic S compounds is promoted; by contrast, C:S ratios between 200 and 400 result in no net changes of SO_4^{2-} concentration in the soil solution. Organic matter with a C:S ratio above 400 induces immobilization of SO_4^{2-} and renders it readily available to plants (Wilhelm, 2009; Lucheta and Lambais, 2012). Therefore, the addition of organic C can increase the amount of SO_4^{2-} immobilized in soil (Saggar et al., 1981).

Oxidation and reduction of sulfur in soil

The biochemical reactions of S in soil are characterized by oxidation and reduction, both of which are of great significance to the material recycling of the soil system. Reduced S^0 must be oxidized to SO_4^{2-} before it can be absorbed by plants. The oxidation of S in soil includes abiotic and biotic oxidation. Abiotic oxidation is mainly controlled by redox potentials, and low-valence S (e.g., S^{2-} , S^0 , SO_3^{2-}) is easily oxidized to SO_4^{2-} because of the low standard potential of S. However, S oxidation in soil is mainly achieved through biochemical oxidation, which differs from chemical oxidation through its involvement of microorganisms. These microorganisms are mainly S-oxidizing bacteria that can completely or partially oxidize low-valence reduced sulfides (e.g., H_2S , S, SO_3^{2-} , thiosulfate ($\text{S}_2\text{O}_3^{2-}$)) to higher-valence sulfides (e.g., final product SO_4^{2-}). The reduction of S in soil is also very important, and oxidation and reduction usually occur simultaneously. In highly reducible soil and sediments, SO_4^{2-} functions as an important electron acceptor and can be reduced to S^{2-} with the participation of microorganisms. The SO_4^{2-} -reducing bacteria exist widely in the environment and reduce high-valence S compounds (such as SO_4^{2-} , SO_3^{2-} , and $\text{S}_2\text{O}_3^{2-}$) and S^0 to low-valence sulfide (H_2S).

Adsorption and desorption of sulfate by soil

Sulfate (SO_4^{2-}) is the main acid-inducing component in acid deposition, and the ability of soil to adsorb and desorb this ion can effectively reflect the sensitivity and tolerance capacity of the soil to acid deposition. Adsorption of SO_4^{2-} in soil can result in the release of OH^- ions from the soil surface, thereby improving the soil's ability to neutralize acid, preventing cation leaching, and delaying the acidification of soil and surface water (Dail and Fitzgerald, 1999). The adsorption mechanisms of SO_4^{2-} are as follows: (1) binding with hydrated oxide, which is mainly characterized by specific adsorption; (2) ligand exchange between SO_4^{2-} and other surface groups of clay, during which SO_4^{2-} can replace hydrated or hydroxyl groups; (3) molecular adsorption; and (4) electrostatic adsorption. The latter two adsorption mechanisms may generally be described as nonspecific adsorption and follow the law of mass conservation (Singh, 1984). Desorption can be regarded as the reverse process of adsorption. Some studies show that soil properties, including iron oxide content, organic matter content, pH, degree of base saturation, aluminum saturation, soluble SO_4^{2-} content, and temperature are the main factors affecting the soil adsorption of SO_4^{2-} . The comprehensive effects of various physicochemical properties in soil could lead to changes in the adsorption capacity of this matrix for SO_4^{2-} .

Availability of sulfur in soil

Many chemical fractions of S exist in soil, and analyzing the fractions distribution of S in soil is of great significance in understanding the chemical cycle of S and its influence on the environmental behavior of other substances. Water-soluble S is a readily available fraction for plant uptake and utilization. Adsorbed S is stable and difficult to leach. The availability of hydrochloric acid-soluble S is less than that of water-soluble and adsorbed S. Available S is the S component in soil that can be absorbed directly

and utilized by plants and usually includes water-soluble S, adsorbed S, and some organic S. Soil available S is the main index used to measure soil S supply capacity. In general, when the available S content in soil is less than 10–16 mg kg⁻¹, crops may face the risk of S deficiency.

Selenium in soil

Selenium sources in soil

Weathering of parent materials and rocks is the major source of Se in soil. The Se content of different rocks is quite different, and the Se content in soil formed by sedimentary rocks, igneous rocks, or black shale is consistently higher than that of basalt and metamorphic rocks. Atmospheric deposition is another important natural source of soil Se. The Se in particles produced by volcanic eruptions and forest fires accounts for approximately 10% of the natural sources of Se in the atmosphere. Selenium released by bio-mediated volatilization accounts for ~30–50% of the annual total Se emissions (Zoller et al., 1974) and is another important source of Se in the atmosphere. Selenium entering the atmosphere eventually re-enters the soil through deposition. Coal mining, thermal power generation, combustion of fossil fuels, and the use of mineral fertilizers or Se-enriched organic materials is a key factor leading to Se in rock minerals or Se-containing agricultural wastes entering the soil, which are important anthropogenic sources of soil Se.

Selenium contents in soil

Selenium is a rare and dispersed element that lies between the oxygen-group element S and the metal element Te (tellurium). The Se content of the Earth's crust is very small. Considering the narrow range between the necessary and toxic doses of Se for humans, Tan (1989) defined a grading standard of total Se content in various soil areas as follows: Se < 0.125 mg kg⁻¹ refers to an Se-deficient area, Se = 0.125–0.175 mg kg⁻¹ refers to an Se-marginal area, Se = 0.175–0.45 mg kg⁻¹ refers to an Se-sufficient area, Se = 0.45–2.0 mg kg⁻¹ refers to an Se-rich area, and Se > 3.0 mg kg⁻¹ refers to a seleniferous area. Because it is influenced by soil parent materials, climate (e.g., temperature and precipitation), and topographic conditions (e.g., slope and altitude), the global distribution of soil Se is extremely uneven and seleniferous and Se-deficient areas exist side by side. The Se content in most soils in the world ranges from 0.01 to 2.00 mg kg⁻¹, with an average of 0.40 mg kg⁻¹, although the soil Se content in some seleniferous areas can reach 1200 mg kg⁻¹. The Se-rich areas are mainly in Wyoming and South Dakota in the United States (20–40 mg kg⁻¹; Gerla et al., 2011), Enshi and Ziyang in China (36.69–79.08 mg kg⁻¹; Dinh et al., 2018), Punjab in India (Dhillon and Dhillon, 2003), and several other regions. However, approximately 40 countries and regions in the world are Se-deficient; these countries and regions are mainly in the middle latitudes and latitudes above 30 degrees in both the southern and northern hemispheres (e.g., Finland, central Serbia, and parts of the Congo). Overall, the global area of Se-deficient soil is larger than that of Se-rich soil (Dhillon and Dhillon, 2003).

Selenium speciation in soil

The chemical forms and valence of soil Se affect whether it can be absorbed and utilized by plants. Under natural conditions, Se in soil often exists in different chemical forms and valence states, and the fractions or valence states of Se could transform with changes in environmental conditions.

Selenium species in soil

Selenium is a valence-variable element that often exists in four valence states, namely, hexavalent (e.g., selenate, Se(VI)), tetravalent (e.g., selenite, Se(IV)), nonvalent (e.g., elemental, Se⁰), and negative divalent (e.g., selenide, Se(–II)). In well-ventilated alkaline soil, Se mainly exists in soil solution in the form of Se(VI) or combined with soil particles by electrostatic adsorption (Wang et al., 2012). Selenate is often reduced to selenite in acidic and reducing soils; thus, Se mainly exists in such soil solutions in the form of Se(IV), adsorbed on the surface of soil particles or combined with solid components of the soil (e.g., iron (Fe) and manganese (Mn) oxides, hydrated oxides, and organic matter). Elemental Se (Se⁰) is often enveloped by organic matter or exists in soil in the form of a residue. Inorganic-bound Se(–II) mainly exists as a precipitate, while organic-bound Se(–II) is often in the soil solution, and leaves soil as a volatile component (e.g., dimethyl Se), or exists in organic matter combined with soil solids (Zhang and Moore, 1996).

Distribution of selenium fractions in soil

Soil Se can be divided into different forms according to the degree of binding of Se with soil components determined by different extraction and classification procedures. A widely used method for grading soil Se forms is five-step sequential extraction (Wang et al., 2012). In this method, soil Se can be divided according to the difficulty of extraction into water-soluble (SOL-), exchangeable and carbonate-bound (EXC-), iron-manganese oxide-bound (FMO-), organic-bound (OM-), and residual (RES-) Se. Organic-bound Se can be transformed into inorganic Se, which can be directly absorbed and utilized by crops through mineralization and it plays an important role in the geochemical cycle of Se. Therefore, organic-bound Se can be further divided into humic acid-bound Se (HA-Se) and fulvic acid-bound Se (FA-Se) according to its acid solubility; FA-Se, in turn, can be further subdivided into hydrophilic Se (Hy-Se) and hydrophobic Se (HON-Se).

Different types of soils have different compositions and properties, and the proportion of Se in each form is different. The distribution of Se fractions in natural Se-rich soil is different from that in other soils. In natural Se-rich soil, the stable organic-bound and residual fractions are the main fractions of Se in soil (~80–90% of the total Se in soil), while the water-soluble and exchangeable Se fraction (i.e., bioavailable Se) account for less than 5% of total Se (Wang et al., 2012). Although the sum of residual and organic-bound Se fractions account for over 80% of the total soil Se in low-Se soil, the proportion of bioavailable Se in the total Se varies from only 1.1% to 20% depending on the soil properties and environmental conditions (Zhang and Moore, 1996).

Transformation processes of selenium in soil

With changes of environmental conditions, Se in soil undergoes a series of transformations such as adsorption-desorption, dissolution-precipitation, oxidation-reduction, complexation, and volatilization reactions in terms of its form and valence state (Fig. 2). Therefore, understanding the chemical transformation of Se in soil is of great importance in evaluating the supply capacity or bioavailability of Se in this matrix.

Adsorption-desorption reaction

Selenate and selenite are the main forms of Se absorbed by crops. After entering the soil, exogenous selenate (Se(VI)) forms an outer-sphere complex with the soil through electrostatic interaction and physical combination. Selenite (Se(IV)) diffuses into the inner lattice of soil mainly through micropores and forms a relatively tight inner-sphere complex with iron and manganese oxides or organic matter in soil. Because the adsorption strength of the inner sphere is stronger than that of the outer sphere, the mobility and bioavailability of selenite in soil are significantly less than those of selenate (Sharma et al., 2015). Moreover, competitive anions co-existing in the soil solution, such as PO_4^{3-} , SO_4^{2-} , and nitrate (NO_3^-), have a remarkable impact on the adsorption of Se (especially Se(IV)) in soil; PO_4^{3-} (with low affinity), for example, has been observed to have a greater effect on the adsorption of Se than SO_4^{2-} (Goh and Lim, 2004). Desorption also plays an important role in the fractional transformation of Se in soil. The rate of desorption of Se in soil is negatively correlated with the content of metal(hydroxide) oxides, but positively correlated with soil pH; indicating that the desorption of Se in soil is also affected by soil properties.

Dissolution-precipitation reaction

The dissolution-precipitation reaction directly affects the fraction of Se in the soil and the difficulty of crop utilization. Soil Se can be transformed into residual fraction and difficult for plants to uptake and utilize. At low pH, Se(IV) can be reduced to Se^0 or Se—S precipitates in sulfide solution; such precipitation is more significant at lower pH than that at higher pH. However, the precipitation of Se^0 or metal selenides (e.g., FeSe and FeSe_2) also limits the dissolution of Se in soil under reducing conditions. The microbial degradation of organic matter (Eswayah et al., 2016) and reductive dissolution of soil minerals (e.g., ferric hydroxide)

Fig. 2 Chemical behavior of Se in soil (Dinh et al., 2019).

(Shaheen et al., 2017) lead to the re-release of bound Se into the soil solution, thereby improving its bioavailability. Small-molecule organic acids produced by returning organic materials to the field or secretion of plant roots can also dissolve the Se fixed by soil and prevent it from being adsorbed and coprecipitated by iron/aluminum oxide/hydroxides (Dinh et al., 2017).

Oxidation-reduction reaction

Under anaerobic conditions, Se(VI) can be gradually reduced to Se⁰ by the action of some bacteria, and further reduced to Se(–II) by the assimilation of microorganisms (Eswayah et al., 2016). Moreover, Se(VI) can be reduced to Se⁰ by the dissimilation of chemical/biochemical reducing agents. The existence of SO₄^{2–} and iron oxide contributes to the reduction of Se(VI) (Olegario et al., 2010), but NO₃[–] has an inhibitory effect on this process (Bassil et al., 2018). Although the oxidation of Se is mainly mediated by microorganisms, it can also be promoted by abiotic factors (Bassil et al., 2018). The Se⁰ and Se(IV) forms can be oxidized by soil microorganisms under aerobic conditions, and the abiotic oxidation of Se takes place in the presence of peroxodisulfate ions and synthetic manganese oxide and birnessite (Scott and Morgan, 1996). Nevertheless, the rate of biological oxidation of Se(IV) is generally lower than the biological reduction of Se(VI) (Bassil et al., 2018), which means Se tends to be reduced rather than oxidized.

Complexation reaction

Selenium can be complexed with organic matter and iron and/or manganese oxides in soil, and the complexation strength of soil for Se(IV) is greater than that for Se(VI). Therefore, selenite is more easily fixed by soil components than selenate (Dinh et al., 2017). Soil OM increases sorption sites, which directly facilitate complexation with Se (Dinh et al., 2017). Soil microorganisms can promote the fixation of Se(IV) in soil and promote reduction of the fixed Se(IV). In addition, because the functional groups of organic compounds (e.g., hydroxyl, carboxyl, and carbonyl) and Se oxyanions are negatively charged, soil Se and organic matter can be fixed by forming a ternary complex (e.g., Se–HM–OM) through positively charged metal bridge bonds (Dinh et al., 2017).

Volatilization reaction

Methylation is the key process of the volatilization and removal of Se in soil. Two mechanisms of soil Se methylation have been identified, namely, chemical and biological; of these the biological process is dominant. The existing forms of Se, microbial activity, organic matter content, temperature, and water content in the soil affect the methylation process of soil Se. In addition to bacteria, microalgae, and fungi, the biomethylation of soil Se can also be mediated by plants (Terry et al., 2000). The demethylation process of Se is opposite to its methylation process, and can occur under both aerobic and anaerobic conditions. Under anaerobic conditions, dimethyl selenide is rapidly demethylated by microorganisms to produce H₂Se (Eswayah et al., 2016). By comparison, Se(VI) is the final product of demethylation under aerobic conditions (Bolan et al., 2014).

Bioavailability of selenium in soil

The concept of ‘bioavailability’ was first proposed in the context of the water environment and is used to describe the degree of utilization of pollutants during bio-transmission or bio-reaction. Bioavailable Se refers to Se in soil that can be directly absorbed and utilized by plants, which is the main factor that determines the Se content of the plants (Terry et al., 2000). The total amount of Se does not indicate and evaluate the bioavailability of Se in soil, but its form, especially the content of bioavailable Se, is the key to determining its mobility and toxicity.

Selenium in soil often exists in different chemical forms and valence states, and its solubility, mobility, and bioavailability in different forms and valences are quite different. Elemental Se and Se(–II), for example, are insoluble in water and difficult to absorb and utilize by plants; by contrast, Se(IV) and Se(VI) are water-soluble and are the main forms of Se absorbed by crops (Dinh et al., 2018). Moreover, because Se(IV) is easily adsorbed by soil components (e.g., clay minerals and organic matter), the mobility and bioavailability of Se(VI) in soil are higher than those of Se(IV) (Wang et al., 2012).

Among the five fractions of soil Se, SOL-Se has the strongest mobility and is most easily absorbed by plants. The EXC-Se refers to Se(IV) combined with hydrated oxides or adsorbed on the surfaces of clay minerals and humus. The bioavailability of EXC-Se is less than that of SOL-Se, but the former can be converted into the latter and absorbed by plants. Therefore, the sum of SOL-Se and EXC-Se content is often regarded as the plant-available Se content in soil. The OM-Se in soil mainly includes FA-Se and HA-Se. Whereas HA-Se is stable in structure and difficult to decompose and utilize, FA-Se has a low molecular weight and can easily be mineralized into inorganic Se and small-molecule organic Se, which can be absorbed and utilized by crops (Dinh et al., 2017). In addition to the form and valence of soil Se, soil physicochemical properties (e.g., pH, redox potential (Eh), texture, organic matter, co-existing ions), agronomic measures, and climatic conditions also indirectly affect the bioavailability of Se in soil. These should all be considered in evaluating the bioavailability of Se in soil either in phytoremediation or biofortification.

Interaction between sulfur and selenium in soil

In anaerobic conditions, S usually co-exists with Se; in natural aerobic environments, low-valence S is usually oxidized into SO₃^{2–} and SO₄^{2–} and then enters the ocean through the action of surface runoff in the water system. Selenium can easily be oxidized to

Se⁰ and Se(IV) but not Se(VI). Therefore, Se exist mostly in stable fractions in soil. Furthermore, the production of volatile Se compounds is also affected by S, and different forms of S exert different influences on this process. For example, large concentrations of SO₃²⁻ or SO₄²⁻ can almost completely inhibit the formation of dimethyl selenide (DMSe) from selenite, while sulfide can inhibit DMSe formation to a small extent only.

The amount and strength of S and Se adsorption on soil components are different. Iron or aluminum oxides in soil are the main adsorbents of SO₄²⁻, and the adsorbed SO₄²⁻ can easily be replaced by other anions. By comparison, the adsorption of Se by soil depends on its oxidation state but it can also easily be achieved by iron or aluminum oxide. The order of adsorption capacity of iron oxide for some inorganic anions is as follows: orthophosphate (H₂PO₄⁻) > arsenate (H₂AsO₄⁻) = SeO₃²⁻ > silicate (H₄SiO₄) > molybdate (MoO₄²⁻) > SO₄²⁻ > SeO₄²⁻ > chloride (Cl⁻) = NO₃⁻ (Ryden et al., 1987). This order indicates that the affinity of adsorption sites on iron oxide for SO₄²⁻ is between those of SeO₃²⁻ and SeO₄²⁻. Moreover, Se adsorbed in soil can be exchanged by SO₄²⁻, which can significantly weaken the adsorption of Se by iron oxides. Consequently, there must be competition for adsorption sites between SO₄²⁻ and SeO₃²⁻ or SeO₄²⁻, thus affecting the adsorption of selenite and selenate on the soil solid surface and their bioavailability. However, the interactions between S and Se in soil are related to the soil types, plant species, S and Se concentrations, and so on. A systematic understanding of the mechanism of competition between S and Se in soil is currently lacking.

Conclusion

Sulfur and Se undergo a series of chemical processes, such as oxidation-reduction, precipitation-dissolution, and adsorption-desorption, in soil, which leads to continuous changes in their speciation and valence state. These variations are the main challenges in research on the interactions of these two elements. The competition mechanism of S and Se in soil remains unclear, and most previous studies focused only on the interaction between SO₄²⁻ and SeO₄²⁻ during plant uptake. Moreover, the influence of interactions between S and Se on transformation of their speciation in soil has rarely been reported. Scanning electron microscopy, polymerase chain reaction-denaturing gradient gel electrophoresis, 16SrDNA, synchrotron radiation, and other new research methods or technical means should be used to explore the enzymology, microbiology, and soil chemistry of the interactions between S and Se in future research. Such efforts will be of great significance in advancing the understanding of the interactions between S and Se in soil systems and guiding the rational application of inorganic fertilizers and biofortification of Se in crops.

Abstract

Arsenic (As) is a toxic metalloid for all living organisms and is a global concern due to its adverse effect on human health. Humans are mainly exposed to As through the consumption of As-contaminated drinking water and food crops. Apart from drinking water, As-contaminated food crops have become a major route of As entrance into the human body due to As contamination of the agricultural soil from both natural and anthropogenic sources. The transformative behavior of As in the soil, especially in paddy soil, is a complex process that needs better understanding for efficient removal of As from the contaminated paddy soils. This chapter provides current knowledge on As behavior in farmland soil, and special emphasis has been given to different remediation approaches for mitigating As accumulation in rice.

Key points

- Some farmland soils in different parts of the world exceeded the European Union recommended level (20 mg kg^{-1}) of As in agricultural soils.
- Soil pH, redox potential, organic matter and nutrient elements like nitrogen, phosphorus, silicon and sulfur affect As transformation and translocation to plants.
- Among the cereal crops rice is more susceptible to As contamination because of increased As mobilization in the submerged paddy soil.
- Alternate wetting and drying irrigation, Fe- or Mn-modified biochar and silicon fertilizer are some efficient mitigation strategies of As contamination in farmland soil.

Introduction

Arsenic (As) is poisonous and carcinogenic to living organisms yet is ubiquitous in the geosphere. Humans are potentially exposed to As mainly through drinking water and food crops contaminated by both natural and anthropogenic activities. Increased contamination of As in groundwater has been a worldwide concern in the last few years with more than 70 countries reporting As contamination. This means an As-induced potential health risk for an estimated 150 million people globally (Brammer and Ravenscroft, 2009). The situation is particularly alarming in South-East Asian countries including Bangladesh, in areas of India, Nepal, Myanmar, Pakistan, Vietnam, Laos, Cambodia, Indonesia and China (Rahman et al., 2009). Apart from increased concentrations in drinking water, As contamination has become a global human health issue due to elevated levels in the agro-ecosystems and subsequent accumulation in food crops. For example, As-polluted irrigation water has resulted in extensive contamination in paddy soils of many Asian countries. The anaerobic environments in flooded paddy soils promote As mobilization, causing increased bioavailability to rice (*Oryza sativa* L.) plants compared to other cereal crops. About half of the world's population consume rice as their staple food making contaminated rice grains a serious health hazard globally for humans. Increased As in paddy soil is not only a threat to food safety but also induces phytotoxicity in rice plants and considerable loss in grain yield, threatening food security. Thus, remediation of As polluted soil has been a global research focus over the last few decades.

The transformative behavior of As in soil involves complex processes regulated by several soil properties such as soil pH, redox potential (Eh), soil texture, cation exchange capacity (CEC), organic matter (OM), oxidation state of iron (Fe) and microbial activity (Nath et al., 2014; Chen et al., 2016). Precise understanding of the soil factors that determine bioavailability of As in farmland soil is crucial for developing successful mitigation strategies. Among the farmland soils, paddy soil needs special attention as rice is grown throughout the world and feeds more than half of the world population. Moreover, the submerged condition which exists only in paddy soil favors As mobilization and increased accumulation in rice grains. This chapter addresses current knowledge on the remediation of As from farmland soil, and in particular paddy soil. In addition, As biogeochemical cycling, the transport mechanism in rice and factors associated with As mobilization in paddy soil are also discussed to provide a better understanding of As remediation in paddy soil.

Occurrence, distribution, and geochemistry of arsenic

Arsenic is a toxic metalloid which belongs to the group VA in the periodic table and exists naturally in the environment. Arsenic ranks 20th among the elements in terms of abundance and its concentration varies between 1.5 and 5 mg kg^{-1} in the Earth's crust (Rahaman et al., 2021). Although, this is a small amount and it is rarely in elemental form, it is a constituent of more than 200 minerals (Upadhyaya and Roychoudhury, 2022) and exists as inorganic forms. Sulfur (S), iron and phosphate minerals are major sources of As in the form of arsenates (60%), sulfides and sulfosalts (20%), and other forms such as arseniurates, arsenites, arsenides, silicates and oxides (20%) (Mandal and Suzuki, 2002; Upadhyaya and Roychoudhury, 2022). The major As bearing primary minerals are arsenopyrite (FeAsS), realgar (As_4S_4), orpiment (As_2S_3), cobaltite (CoAsS), niccolite (NiAs), arsenolite (As_2O_3), tennantite ($(\text{Cu,Fe})_{12}\text{As}_4\text{S}_{13}$), haematolite ($(\text{Mn,Mg})_4\text{Al}(\text{AsO}_4)(\text{OH})_8$), and scorodite ($\text{FeAsO}_4 \cdot 2\text{H}_2\text{O}$). In the Earth's crust, arsenopyrite is the dominant form of mineral As under elevated temperature conditions (Rahaman et al., 2021). Igneous, metamorphic, and sedimentary rocks are another natural source of As. Metamorphic ($\sim 5 \text{ mg kg}^{-1}$) and sedimentary rocks ($5\text{--}10 \text{ mg kg}^{-1}$) have larger concentrations of As than igneous rocks (1.5 mg kg^{-1}).

In the environment, As contamination primarily occurs from the three sources: hydrothermal activity, ore deposits and Cenozoic sediments (Masuda, 2018). In some countries of Latin America, United States and New Zealand, the major source of As is hydrothermal activity like volcanic eruptions and hot springs. Ore deposits are the second major source of As contamination and mainly result from mining activities, leading to As contamination in both the hydrosphere and pedosphere. This has caused As contamination in many parts of South Africa, Zimbabwe, Thailand and China. The third major cause of As contamination is Cenozoic sediments that cause As contamination in the aquifer. This is the origin of As contamination in many South Asian countries including Bangladesh, India and Pakistan (Masuda, 2018). In addition, other natural sources that contribute to As

contamination include forest fires, wind-blown dust, and sea salt. Other than these natural sources, human activities also cause As contamination in the environment. For example, use of As bearing pesticides in the twentieth century caused severe As contamination in many countries of the world. Although, the use of these pesticides has decreased, especially in the developing countries, but alloys containing As are still being used in semiconductors (Masuda, 2018). Other anthropogenic sources include mining activities, metallurgy, combustion of fossil fuels, urban waste, and cattle farming. It is estimated that the global annual contribution of anthropogenic sources to As contamination is about 75–100 metric tonnes.

The mobilization processes involved in natural As pollution of the soil and water are reductive dissolution, alkali desorption, sulfide oxidation and geothermal activity (Ravenscroft, 2007). Reductive dissolution is the most common mode which occurs when As is adsorbed to iron oxyhydroxides in sediments. Reductive dissolution mainly occurs in humid areas, while alkali desorption occurs in arid regions (Ravenscroft, 2007). In arid soils the presence of small clay, organic matter and free Fe contents, and large negative surface charges are attributed to the desorption of arsenic, mainly As(V) (Kandakji et al., 2015; Rahman et al., 2019).

In organic and inorganic compounds As mainly exists in four oxidation states: arsenate (+5), arsenite (+3), arsenic (0) and arsenide (−3). Arsenic in −3 (e.g. arsines and metal arsines) and 0 oxidation states are unstable in the soil. Arsenate is the dominant form under aerobic condition which exists as arsenic acid (H_3AsO_4) and occurs at pH 2–3. With an increase in pH (3–11), H_3AsO_4 dissociates to $\text{H}_2\text{AsO}_4^{4-}$ (dihydrogen arsenate) and HAsO_4^{2-} (hydrogen arsenate). In anaerobic conditions arsenite is the predominant form of As found as H_3AsO_3 , arsenous acid. Arsenic in soil can undergo a methylation process resulting in organic As species mainly monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA).

Arsenic in agricultural soil

In the pedosphere, As concentration ranges between 10 and 40 mg kg^{-1} from uncontaminated natural sources with an average concentration 5–8 mg kg^{-1} (Mandal and Suzuki, 2002). The concentration of As in soil varies with the soil horizon, soil type and lithology. In rare cases, some soils have very large concentrations of As (0.1–2%) from either geological or anthropogenic sources (Ongley et al., 2007). These soils may have detrimental effects on human health and the wider ecosystem. Geographically there is a wide variation in the magnitude of As contamination in agricultural soils. Table 1 represents a global scenario of As contamination in agricultural soils. In farmland soil As contamination comes from both natural and anthropogenic sources. Weathered rocks and alluvial sediments are major natural sources of As contamination. Other than natural sources, use of As contaminated irrigation water largely contributes to the increased As contamination in paddy soil. Anthropogenic activities such as disposal of As-containing effluents, tailings, deposition of metallurgical fumes and metal mining have resulted in As accumulation in the soil and subsequent transport to rice grains in several areas of the world.

Table 1 Arsenic concentrations in agricultural soils across the world.

In paddy soil, As occurs mostly in two inorganic forms: As(V) and As(III). Under flooded conditions As(III) is the dominant form. Small amounts of organic species like MMA, DMA and trimethylarsine (TMA) also occur in paddy soil due to microbial biomethylation of inorganic As. The behavior and fate of As in soil solutions are mainly regulated by its speciation. Inorganic As species are more toxic than organic species; in particular the toxicity of As(III) is greater than As(V). The latter is attributed to the reaction of As(III) with sulfhydryl (–SH) groups of proteins and enzymes which causes a disturbance in cell activities and eventually cell mortality. It is possible that As(III) has a greater mobility than As(V) which causes decreased adsorption on soil particles.

Transport of As from soil to rice grain

Paddy soil remains submerged most of the time during the rice growing period and this environment favors the mobilization of As. In paddy soil under submerged conditions, As(V) is also reduced to As(III) which is more toxic. Under submerged conditions, more than 95% of the As in paddy soil is As(III). The increased bioavailability of As in flooded conditions is attributed to the reductive dissolution of iron oxyhydroxides. Moreover, continuously submerged conditions promotes the abundance of the Fe-reducing bacteria population which further enhances the reductive dissolution of iron hydroxides and related As reduction. The As mobilization from Fe-oxide surfaces can be explained by three mechanisms: (a) site transfer of adsorbed As between liquid and solid phase and subsequent desorption, (b) reduction of Fe(II) to Fe(III), and (c) reduction of As(V) to As(III) from the Fe-oxide-As complex. The crystal structure of As-oxide can also affect As mobilization in the soil solution, where poorly crystallized Fe-oxide restricts As mobilization. Arsenic mobilization forming Fe-oxides in the soil solution can be explained by the following equations.

In paddy soil, As is also transformed into organic forms mainly MMA and DMA through a microbially-induced methylation process. The bioavailability of As species to plants is in the order As(III) > MMA > As(v) > DMA, while the order of toxicity is As(III) > As(V) > MMA > DMA. In plants, As(V) is transferred through phosphate transport channels, whereas As(III) and organic As species are transported by aquaporin channels. The toxicity, solubility and bioavailability of As is largely governed by various soil properties such as OM, pH, mineral oxides, clay content and CEC. Arsenic in the rice plant accumulates in the roots and is then distributed to the different plant parts in the order of root > leaves > shoots > husk > grain.

Factors affecting As transformation and transport in the soil-plant system

Soil pH and redox potential

Soil pH and redox potential largely regulate the mobilization of different forms of As. In soil with high pH, the availability of As is increased by the desorption of As(III) from the negatively charged soil minerals. In acidic soil, As bound with Fe and Al hydroxides is released into the soil solution. Moreover, at low pH, phosphorus (P) and As(V) both compete for the same sorption sites, increasing the mobility of As in the soil matrix.

The submerged conditions of paddy soil decrease redox potential (Eh) to –200 mV, because of depleted oxygen. This soil condition favors the microbially-mediated transformation of Fe oxyhydroxides, which is the key sink of As, and releases the sorbed As into the soil solution. Under negative Eh in flooded conditions, As(V) is reduced to As(III) and the ratio of As(III)/As(V) is high.

Soil organic matter

Soil organic matter (OM) can affect As mobilization both positively and negatively. In the presence of OM, As forms a complex with different organic compounds, reducing the solubility of As and therefore uptake by plants (Kumarathilaka et al., 2018b). On the other hand, negatively charged dissolved organic carbon (DOC) present in OM competes with As for sorption on the surface of Fe-oxyhydroxides, which increases As in the soil solution and plant uptake. Increased DOC also promotes Fe(III)-reducing bacterial activity, which enhances the release of As in soil pore water through the reduction of Fe-oxyhydroxides (Chen et al., 2016). Increased concentration of soluble P in the presence of OM is also responsible for increased As mobilization in the soil.

Microorganisms

Soil microbes are involved in the transformation of As by regulating the oxidation and reduction reactions in soil and methylation of As. The soil microbes involved in this transformation are resistant to As at large concentrations. The microbially-facilitated oxidation of As(III) to As(V) is a detoxification process as the pentavalent form is less toxic than the trivalent form. During the microbial respiration process As(III) acts as an electron donor and is oxidized to As(V). The microbial reduction of NO_3^- or SO_4^{2-} in anerobic conditions also causes the oxidation of As(III). Alternatively, microbial reduction of As(V) occurs when As(V) is used as an electron acceptor which releases As(III) in the soil matrix. Apart from oxidation-reduction, As methylation is caused by different microorganisms including bacteria, cyanobacteria and algae (Kuehnelt and Goessler, 2003). Microbes also affect the mobilization

of As in the root zone by manipulating the oxidation-reduction of Fe. The microbially-mediated reduction of Fe oxides (ferric) releases the adsorbed As(V) in the soil solution and increases its availability. The released As(V) is reduced to As(III), which is subjected to methylation by an abundance of *arsC* (arsenate reductase) and *arsM* (arsenite methyltransferase) genes in the flooded paddy soil. Alternatively, Fe-oxidizing microbes cause the oxidation of ferrous Fe in the presence of NO_3^- which promotes the precipitation or adsorption of As with ferric minerals in the soil and reduces As availability in the rice rhizosphere, and therefore the uptake by rice. This means the microbial transformation of As could be manipulated for the bioremediation of As in paddy soil.

Clay mineralogy

The low redox potential in paddy soil increases the flocculation and dispersion of clay particles which leads to their downward movement. The deposition of clay particles below the plow zone, and other mechanical activities during the rice growing period, leads to the formation of hard plow pans. Clay minerals are negatively charged fine particles with a large surface area, where As bearing Fe-oxyhydroxides precipitate. The precipitation of Fe-oxyhydroxides reduces As availability in soil solutions and consequently its uptake by the rice plant. The sorption and speciation of As in paddy soil can vary with the crystal structure and type of clay minerals. Deposition of different secondary minerals on the surface of clay minerals can alter their physico-chemical properties, which subsequently affect their ability to adsorb As (Uddin, 2017). However, the long-term interaction of As with various clay minerals such as kaolinite, montmorillonite, and illite are not fully understood and requires further study.

Interaction with soil nutrients

Phosphorus

Phosphorus (P) has a strong relationship with soil As availability, uptake and translocation in rice plants. Arsenate is analogous to phosphate in chemical form, and both adsorb onto the surface of Fe-oxide through a ligand exchange mechanism. The As(V) is absorbed by the rice plant through the same pathway as phosphate. Therefore, the competition for sorption sites between these two ions can result in two different effects. Phosphorus can increase or decrease As availability in soil and subsequently increase or decrease its uptake by plants. Deng et al. (2020) reported different effects from phosphate on As transformation in paddy soil under suboxic and anoxic conditions. Under suboxic conditions, phosphate replaces As(V) from the adsorption sites and increases the concentration of As(V) in the soil solution. In anoxic conditions, phosphate promotes the reduction of Fe and As through increased microbial activity, increasing As(III) concentration in the soil solution at both acidic and neutral or alkaline pH. However, some studies have reported that phosphate fertilizer can suppress As uptake by rice grains when the available P concentration is large in the soil solution and by forming amorphous Fe minerals where As(V) coprecipitates. The interaction of phosphate and As is governed by soil factors such as soil Eh, pH, P availability, organic ligands and Fe minerals (Deng et al., 2020). Therefore, further study is required for a clear and quantitative understanding of the effects of phosphate on As mobility in the soil and its transfer to rice grains in a complex soil system.

Silicon

Silicon (Si) is naturally present in the paddy soil. It is also applied to reduce the effect of different abiotic stresses, such as drought, on the rice plant. In an aqueous solution of paddy soil, Si is released as silicic acid (H_4SiO_4) which has a strong affinity to Fe oxyhydroxides. Silicic acid (H_4SiO_4 , $\text{pK}_a = 9.8$) and arsenite (H_3AsO_3 , $\text{pK}_a = 9.2$) are translocated into the rice plant by the same transporters (Ma et al., 2008). Thus, H_4SiO_4 competes with As (III) which reduces the As(III) uptake by the rice plant. The transporters regulate As translocation within the rice tissue parts only and have no ability to regulate root As absorption, whereas Si in the soil solution affects As(III) uptake by the root (Zhao et al., 2010). Both H_4SiO_4 and As(III) compete for the same adsorption sites which releases As(III) into the soil solution and subsequently results in the increased uptake of As(III) by rice plants (Kumarathilaka et al., 2018a). Silicic acid may also increase the organic As species (DMA) in the soil solution which is less toxic through the release of sorbed DMA and increase in As(III) methylation (Limmer et al., 2018). This warrants further investigation to understand the probable mechanisms of As immobilization when Si is applied to paddy soil.

Nitrate

Nitrate (NO_3^-) plays an important role in As speciation in the soil solution by regulating the reduction of Fe. Nitrate promotes the oxidation of Fe^{2+} and inhibits the reduction of Fe^{3+} in the soil solution. This process promotes As sequestration by binding As in the secondary minerals of Fe and reduces the As availability in paddy soil. In anaerobic conditions nitrate creates the oxidation of As(III) to As(V) followed by adsorption of As(V) on the surface of Fe-oxyhydroxides.

Sulfur

Sulfur is an essential nutrient element for plants that can immobilize As in the soil. In soil solutions, S is present as SO_4^{2-} which is transformed to sulfide (S^{2-}) with the decrease in Eh under anoxic conditions. The sulfide reacts with As(III) and precipitates as As_2S_3 (arsenic trisulfide) or AsS (arsenic monosulfide). Sulfates also compete with As(V) in metabolism and transport, which reduces the translocation of As in cell membranes. In the rhizosphere, As binds with organosulfur compounds through a chelation process that immobilizes As in the soil solution. There is evidence of S-induced Fe plaque formation on the root surface which restricts As uptake by the rice plant. Thus, S fertilizer in paddy soil can play an important role in As immobilization and uptake by rice plants.

Arsenic phytotoxicity in rice plants

Arsenic is not only toxic to human health, but also has an adverse effect on crop plants. Under As toxicity, plants suffer from oxidative stress due to excessive production and accumulation of reactive oxygen species (ROS) and hydrogen peroxide (H_2O_2). It also inhibits adenosine triphosphate (ATP) production and carbohydrate assimilation in rice grains which result in poor grain yield. Arsenic toxicity may cause reduced seed germination, stunted plant growth, brown spot and scorched leaves (Moulick et al., 2018).

Arsenic in rice grains

Arsenic content of rice grains varies largely with rice cultivars and locations as rice is cultivated in about 100 countries with more than 120,000 cultivars. Table 2 shows a global scenario of As concentration in rice grains where it varies from as low as 0.03 mg kg^{-1} to as high as 0.77 mg kg^{-1} . The concentration of As in rice grains differs widely with geographic location, cultivars and growing conditions. Zavala and Duxbury (2008) reported that in Bangladesh, increased As concentration in rice grains resulted from As-contaminated irrigation water, rather than soil As, whereas in the southern United States it was caused by the excessive use of As-containing agrochemicals and subsequent accumulation in the soil. Williams et al. (2005) conducted a global level investigation on As speciation and reported that inorganic As was the dominant fraction in rice grains of Bangladesh ($64 \pm 1\%$), India ($80 \pm 3\%$) and Europe ($81 \pm 4\%$), whereas in the United States, the dominant fraction was organic As species (DMA) and inorganic fractions were only $42 \pm 5\%$ of the total. The color and size of the rice grains also contribute to the variation in As concentration. For example, one study reported higher As concentration in the extra-long slender Indian basmati rice than in short-bold brown rice. In rice grains most As accumulates in the external layer of the grain called bran which is removed in white rice during polishing yet stays intact in brown rice. Consequently, As concentration in brown rice is higher than in white rice. One study reported that 10% polishing of the rice grain can decrease the total As by 61–66% and inorganic As by 51–70%. However, polishing can affect other essential nutrient content in rice grains. Arsenic translocation in rice grains is also affected by the growing season. Dry season rice contains more As than that grown in the wet monsoon season. This seasonal variability is attributed to the use of As-polluted groundwater for irrigation in the dry season, which increases As availability, followed by increased accumulation in the rice grain. Together with environmental factors, As content of rice grains is also governed by genetic variation. One study reported that environment (E), genotype (G) and $G \times E$ interaction caused 69–80, 9–10 and 10–21% variation, respectively in rice grain As.

Arsenic exposure and human health risk

Arsenic contamination in groundwater and agricultural soil has been a global concern due to its subsequent translocation in food grains, especially rice. In many parts of the world, including Bangladesh and India, the groundwater As concentration has exceeded the maximum tolerable limit of As (0.01 mg kg^{-1}) in drinking water (Rahman et al., 2009). In China the background value of soil As (11.2 mg kg^{-1}) exceeded the global average As concentration by (5–10 mg kg^{-1}). The increased contamination of As in soil and groundwater has resulted in increased contamination in food crops, especially rice. Dietary intake of rice has been a major pathway of As exposure in many countries where rice is the main diet. A study from China reported that 2.5% of 160 polished rice samples surpassed the upper limit of inorganic As (0.1 mg kg^{-1}) recommended for infants and children by the European Union.

Arsenic contamination in rice grains poses a potential health risk for humans through dietary intake. The International Agency for Research on Cancer (IARC) has categorized arsenic as a group I carcinogen. Arsenic-induced skin, lung, bladder, kidney, liver, and prostate cancers in humans have been widely reported. Many cell and organ activities in the human body are disrupted by As toxicity. Arsenic is also related to ischemic heart disease in humans.

Remediation strategies for As

Water management

Arsenic contaminated irrigation water has caused As accumulation in paddy soils of many countries, especially in Southeast Asia. The water requirement of rice crops is much greater than other grain crops, and rice is normally cultivated under flooded conditions. However, rice crops do not require continuous standing water throughout their life cycle. Therefore, alternate wetting and drying (AWD) is an efficient irrigation practice that not only saves water but also reduces As mobilization in paddy soil and uptake by the rice. One study found that AWD reduced As availability by 86%, 55% and 41% in pore water, root plaque and rice grains, respectively. The AWD technique promotes soil aeration which favors the oxidation of As(III) to As(V), the less toxic form (Takahashi et al., 2004). Increased aeration also increases Fe plaque formation in the root zone of rice which reduces As uptake by the crop.

Organic amendments

Biochar

Biochar is the stable, carbon rich material produced from a wide range of biomass created by pyrolysis, which has several agronomic, environmental, and economic advantages as a soil amendment. A further benefit to soil health is biochar's capacity for metal adsorption due to its large surface area, high porosity, and diverse functional groups. However, the efficacy of biochar on metal remediation varies widely due to the variation in feedstock and pyrolysis process, biochar properties, soil type, microbial activity and rate of application. Recently, biochar has been modified by various chemical and physical treatments to improve the immobilization efficiency of target metals. Biochar performs better for the immobilization and adsorption of cationic metals such as cadmium (Cd), lead (Pb), zinc (Zn), and chromium (Cr), while this effect is not as prominent on anions like phosphate and As. In some cases, biochar even increases the mobilization of anionic metals. Biochar application causes several chemical changes in the soil, for example an increase in soil pH, DOC, pore water phosphate, microbial activity and the reduction of Fe and Mn, which favors the mobilization of soil As. Biochar rich in P, increases the soil solution phosphate which desorbs As(V) from the solid phase into the soil solution from competition between phosphate and As(V) for adsorption sites. Biochar releases DOC which also contributes to As mobilization through reductive dissolution of Fe oxyhydroxides and subsequent desorption of the As bound to them. Biochar induced As mobilization is attributed to the increased phosphate and DOC concentration in the soil solution and increased reduction of Fe due to increase in Fe-reducing bacteria population. However, some studies have found that biochar can substantially immobilize soil As by forming Fe—Mn plaque on the rice root. Moreover, the As immobilization efficiency of biochar can be increased by modifying the biochar. Surface modification of biochar with Fe- and manganese-based materials appears efficient for As remediation in paddy soils with their greater affinity for As (Zhang et al., 2022). Among Fe-based materials, iron oxide and nano zero valent iron (nZVI) appeared as the most promising, compared to other iron-based materials like FeCl₃, ferric chloride (Wu et al., 2018). Application of biochar, modified with different iron-based materials such as Fe-oxyhydroxy sulfate, FeCl₃ and ZVI, reduced the NaHCO₃-extractable As in the soil solution by 14–30, 101–28, and 17–35%, respectively (Wu et al., 2018). Biochar modified with manganese oxide is also an efficient As immobilization agent in soil by increasing the hydrogen-carbon and oxygen-carbon ratios, hydrophilicity and adsorption capacity of biochar (Yu et al., 2015). One study reported that the application of 2% manganese oxide (MnO) modified biochar significantly reduced As in different parts of the rice plant through oxidation of As(III) to As(V) and subsequent adsorption of As(V) with MnO. The efficacy of biochar on soil As immobilization is also largely affected by the biomass used for biochar production, biochar properties, application rate and soil physicochemical characteristics. Therefore, the interaction of As species with biochar produced from different biomass, needs careful investigation to identify the best rate for field application.

Other organic amendments

Inorganic fertilizers and different organic manures are often applied to improve rice yield and soil health. Organic amendments, especially those rich in cellulose, can immobilize certain metals because of their various functional groups that act as adsorption sites for them. One study revealed that application of cow dung and sugarcane (*Saccharum officinarum* L.) bagasse significantly reduced As contents in rice roots, shoots, grain and husk. In a field study, application of vermicompost with AWD irrigation reduced As accumulation in rice grains by 66% compared to no amendments under flooded conditions. Alternatively, several studies have indicated that organic amendments increased As translocation in rice grains by increasing As mobilization in the soil solution, which was attributed to decreased Eh and increased DOC (Syu et al., 2019). Mobilization of As with organic amendments also varies with the source of amendments. For example, in one example the solubilization of As was greater with livestock droppings than plant-based compost and cow dung. Addition of organic amendments also promotes methylation in paddy soil which acts as an As detoxification mechanism. For example, in a microcosm study soil treated with 2% rice straw showed increased translocation

of methylated As in rice tissue by increasing the microbially-mediated methylation of soil As. Another study also reported increased organic As content in rice grains with a single application of 80 ton ha⁻¹ of olive (*Olea europaea* L.) mill waste compost under field conditions. The use of organic amendments, however, is often hindered by its availability, the large amount required and associated extra cost. The effect of organic amendments on As immobilization is a complex process that requires more study.

Inorganic amendments

Nitrogen fertilizer

Nitrogen (N) is one of the most limiting essential plant nutrients for plant growth and yield and is required in large amounts. The effects of N fertilizer on As mobilization depends on the form of N applied. When N is applied as NO₃⁻ it immobilizes As by inhibiting Fe reduction and increasing Fe oxidation (Liu et al., 2022; Chen et al., 2023). Under anaerobic conditions application of NO₃⁻ fertilizers immobilizes As by inhibiting the reduction of Fe minerals and oxidizing the more mobile and toxic As(III) into the less mobile and toxic As(V) in pore water. However, in wetland soil NO₃⁻ reduction occurs spontaneously due to microbial activity and NO₃⁻ is depleted rapidly. Liu et al. (2022) revealed that NO₃⁻ application reduces the pore As concentration in the early stages (1–3 days) with no major change at the later stages of the incubation period (14 days). Therefore, the benefits of NO₃⁻ on As immobilization in wetland soil particularly in paddy soil is short term and might not be feasible for remediation of paddy soil. In flooded soil, when ammoniacal N fertilizer is applied, the NH₃ is subjected to anaerobic oxidation which occurs simultaneously with Fe₃⁺ reduction. This process is termed Feammox and it releases As adsorbed with Fe oxides. In a field study, Chen et al. (2023) reported that NH₃—N application from urea and ammonium bicarbonate promoted the reduction of As(V) to As(III) in paddy soil and subsequently increased the As concentration in rice grains. The NH₃—N decreased soil pH and Eh which supports Fe³⁺ reduction and increases As mobility. However, in an incubation study, Liu et al. (2022) showed that the application of NH₄Cl decreased As availability in paddy soil with long-term effects. This was explained by the decrease in soil pH which overcomes the Feammox effects on As mobilization. Application of NH₄Cl decreases soil pH with the release of H⁺ through hydrolysis and subsequently increases the positive charge on the surface of Fe minerals which adsorbs As(V). The effect of N fertilizer application on soil As mobilization and speciation is complex, and is affected by the source of N and soil properties such as pH, Eh, organic carbon (OC) and Fe-oxide content. More studies are needed under field conditions in a complex soil system to obtain better insight on the effect of N fertilizer application on mitigating As availability in paddy soil.

Phosphorus fertilizer

Phosphorus is an essential plant nutrient for plant growth and yield. Depending on soil properties and degree of As contamination, phosphate fertilizer application can control As uptake by the rice plant. Because As(V) and PO₄⁻ share the same translocation pathway, the application of P fertilizer can reduce As uptake by the rice plant. Efficacy of P fertilizer on reducing As mobilization in soil and subsequent uptake by the rice plant is governed by three major factors: (i) the competitive interaction between PO₄⁻ and As for adsorption sites in the soil matrix, (ii) the uptake competition between available P and As by the rice root and (iii) the translocation of P from root to shoot (Lee et al., 2016). Research has shown that increased P in the soil solution from external P application reduced As(V) uptake by the rice plant. Alternatively, P application can significantly increase As uptake by the rice plant by increasing As concentration in the soil solution from competition between As(V) and PO₄⁻ for the adsorption sites. Moreover, in flooded rice cultivation systems where the dominant species of As is As(III), P application may show no significant effect on reducing As uptake because PO₄⁻ is not analog of As(III). However, there is a possibility of As(III) oxidation to As(V) even under flooded conditions because of the oxidized rice root zone. Thus, the effect of P amendment on As transformation in flooded paddy soil cannot be disregarded and requires more study. Research is also needed to observe the effect of P fertilizer application on As transformation and uptake by the rice plant under AWD water management, which promotes aeration in the soil.

Sulfur fertilizer

Application of sulfur fertilizer can reduce As mobilization in soil and uptake by the rice plant by changing the chemistry of the rhizosphere soil and inducing As precipitation. In anaerobic conditions, with low Eh and microbial activity, Fe³⁺ and SO₄²⁻ are reduced into Fe²⁺ and S²⁻, respectively, which interact to form nanoparticles of FeS that act as binding sites for As in the soil solution. Moreover, sulfide can immobilize As(III) as As(III)—S phases e.g. As₂S₃. Alternatively, microbes can oxidize S to SO₄²⁻ which prevents the reduction of Mn oxide and Fe hydroxide, ultimately reducing the dissolution of As bound with these compounds (Herath et al., 2018). Sulfur-containing thiol compounds like glutathione and phytochelatin can also immobilize As in the soil solution, forming stable complexes and subsequently reducing As uptake by the rice plant. Some studies have shown that application of S-containing gypsum fertilizer has increased the immobilization of As in paddy soil. The potential of S fertilizer to mitigate As in paddy soil and uptake by rice grains requires long-term field studies for better understanding and large scale application.

Iron supplementation

Application of additional Fe to paddy soil can enhance As immobilization and decrease As uptake by rice plants. Research suggests that Fe supplements can promote As immobilization by stimulating Fe-plaque formation in the rhizosphere. Various iron-based amendments such as Fe sulfate, zero valent Fe, red mud and steel shot can immobilize soil As and reduce As translocation in rice grains. One study reported that application of poorly crystalline iron oxides, FeCl₂·NaNO₃ and FeCl₂ at grain filling stage, decreased As content of rice grains by 54%, 52% and 46%, respectively, in a control sample. The efficacy of Fe amendments on As

immobilization is regulated by the oxidation-reduction reaction in the soil solution. The prolonged anaerobic conditions in paddy soil results in the reduction and dissolution of Fe(III) which eventually releases As(III) into the soil solution. Excessive Fe shows a toxic effect on plant growth, particularly in wetland rice soil. In flooded paddy soil, iron toxicity results from excessive concentration of reduced iron (Fe^{2+}) in the soil solution and its translocation to rice leaves. The excess iron (Fe^{2+}) in rice tissue causes cell damage and physiological disorder due to the production of excessive oxygen radicals. Therefore, the existing amount of Fe in soil should be considered before any additional Fe application.

Manganese supplementation

Manganese (Mn)-based amendments, particularly manganese oxides (MnO_2), can immobilize As by transforming As forms in the soil and successively reducing plant uptake. With their strong reactivity, poor crystal structure and large surface area, manganese oxides are strong oxidants which catalyze the oxidation of As(III) to As(V). The oxidized As(V) becomes immobilized by adsorbing onto the surface of Mn oxides. However, the oxidation of As(III) by manganese oxides is largely influenced by their structure, surface charge properties, mineral crystallinity, abundance and soil pH. The best immobilization effect of manganese oxides has been observed at pH 7–8. At low pH, especially at 4, the effect decreased with the dissolution of manganese oxides. Some synthetic Mn oxides-based amendments such as hausmannite and α - MnO_2 nanorods can significantly reduce As concentration in pore water, and subsequently reduce the accumulation of As in rice plant parts through enhanced oxidation of As(III) to As(V).

Silicon supplementation

Silicon (Si) is second among the elements in the Earth's crust and plays a beneficial role in plant growth, especially when plants suffer from different biotic and abiotic stresses. Research suggests that Si-based amendments reduced As uptake, mainly As(III), by rice plants grown in As-polluted soil. The decreased concentration of As(III) in rice tissues was due to the increased Si concentration downregulating the As(III) transporters, which are the same as salicylic acid transporters (Ma et al., 2008). Silicon also immobilizes As by forming iron plaque in the root zone and changing the Fe- and As-transforming microbial community (Limmer et al., 2018). The effectiveness of Si-based amendments on As varies with the source of Si, application dose, method, time and water management. There are several available inorganic and organic sources of Si such as salicylic acid, silicates of Na, K, Ca and Mg, wollastonite, quartz sand, Si- rich crop residues (e.g. rice and wheat (*Triticum aestivum* L.) straw) and slag-based silicate fertilizers. In a study, the effect of various Si-based organic and inorganic amendments (rice husk, charred rice husk and silicate fertilizers) was examined which showed no significant effect of the amendments on total As concentration in rice grains. They did, however, significantly reduce the inorganic As concentration by increasing organic As concentration, which is less toxic, and charred rice husk performed better than the other amendments. In another study, application of silica gel increased the concentration of organic As (DMA) in rice grains, which was attributed to the increased concentration of DMA in the soil solution from desorption by salicylic acid. The solubility of Si in the amendments also regulates the amelioration effect, because highly soluble Si sources, e.g. silica gel and rice husk decrease As concentration in rice tissues, and less soluble sources like diatomaceous clay increase As concentration. A study on the effect of different Si doses and water management on As accumulation in rice plants showed that a 3 mM Si supplement significantly reduced As uptake by rice plants in soil treated with 300 μM As in pot cultures and the effect was better under aerobic than anaerobic conditions. A field experiment reported that top dressing with Si fertilizer (K_2SiO_3) at booting stage of the rice crop, significantly reduced inorganic As contents in brown rice by increasing Fe-plaque formation in the root zone and retaining As on the Fe plaque. However, some studies showed that Si amendments increased pore water As(III) concentration because of competition for absorption sites in soil minerals with salicylic acid and subsequently increased the grain As concentration. In that case, foliar application of Si could be an alternate method for reducing As translocation in rice. A study on the effect of foliar Si application at different growth stages revealed that the application of Si at tillering reduced inorganic As by 61.4% in the polished rice. The main mechanism of silicon amendments on decreasing As(III) concentration in rice tissues are: i. increased Si concentration in the rice tissue from competitive uptake between Si and As(III), ii. reduced expression of the salicylic acid and As(III) transporters (Lsi1 and Lsi2), and increased methylation of As(III) to organic As. Moreover, in situ immobilization of Si in the rice rhizosphere with formation of amorphous crystalline Fe oxides in the soil and root Fe plaques that act as adsorption sites for As. Silicon fertilization also increases the more As-resistant and As(III)-oxidizing bacteria populations in the rhizosphere. The effects of Si-based amendments on reducing As immobilization in soil solution and uptake by rice involves complex mechanisms that are influenced by several factors with both positive and negative findings. Therefore, more research is required for better understanding of the mechanisms involved before large scale application in the real field conditions.

Seed priming

Plants suffering from severe As stress have reduced plant growth and yield because of changes in physiological processes. Some studies showed that seed priming is effective in reducing As stress on the vegetative growth of rice. One study investigated the effect of potassium humate as a priming agent on rice seed germination and seedling growth in a 50 μM solution of As(III) and As(V) for 12 days and found improved seed germination and seedling growth. These improvements were attributed to increased chlorophyll content, relative water content, antioxidant defense mechanism and nutrient translocation in the rice seedlings. Another study reported that rice seed priming with moringa leaf extract resulted in better germination and improved plant growth, attributed to the increased relative water content in the rice seedlings and reduced electrolyte leakage with a reduction in malondialdehyde content. Seed priming with selenium showed promising effects on rice seed germination, seedling growth, nutrient uptake, physiological

activity and reducing As accumulation in rice tissue parts (Moulick et al., 2016; Moulick et al., 2018). The beneficial effects of selenium for seed priming were possibly from the reduced translocation of As from soil-root-shoot, decreased oxidative stress through increased antioxidant activities and increased uptake of micronutrients. Study results suggest seed priming is promising for alleviating As stress on rice plant growth, particularly at an early stage, and reducing As translocation in rice grains. However, there is limited research on this issue and most of the results are based on the early growth stage of rice in confined conditions which may not reflect a total growth stage study under field conditions. More research is vital to exploit the benefits of seed priming in mitigating As stress in rice plants for practical application.

Phytoremediation

Some aquatic plants (e.g. *Ipomoea aquatic* Forssk, *Marsilea minuta* L. 1771, *Phragmites australis* (Cav.) Trin. ex Steud., *Pteris vittata* L., *Pteris ryukyuensis* Tagawa, *Pteridium Aquilinum* (L.) Kuhn, *Vetiveria zizanioides* (L.) Roberty) have the hyper accumulation ability of metals that can be used for As phytoremediation. Ma et al. (2001) first reported *P. vittata* can translocate As to its aboveground biomass and therefore can be used for soil As removal. A study on the efficacy of *P. vittata* on mitigating As uptake by rice in five different soils showed that rice cultivation with *P. vittata* removed 4–11% total soil As and reduced the phosphate-extractable As by 11–38%, soil pore water As by 18–77%, total As in straw by 17–82%, total As in grain by 22–58% and grain inorganic As by 50–58%. Another study found that growing rice with *M. minuta*, a water fern, significantly reduced As accumulation in rice roots and subsequent accumulation in the above ground biomass. Intercropping of aquatic vegetables (*Ipomoea aquatica* Forssk, *Oenanthe javanica* (Blume) DC, *Sagittaria sagittifolia* L.) with rice showed reduced As concentration, a bioaccumulation factor and translocation factor in brown rice (Huang et al., 2021). However, phytoremediation also affects rice plant growth and yield because of competition between the rice crop and accumulator plant for nutrients, light and space. The disposal of the phytoremediator after harvesting is also an issue of concern. The effectiveness of the phytoremediation technique varies with the growth of hyperaccumulating plants, As accumulation potential, tolerance to As toxicity, concentration and bioavailability of the contaminants to be remediated. The As accumulation potential and tolerance of the accumulator plant to As can be increased by several amendments like plant growth promoting chemicals and fertilizers, biochar and certain microbes (Franchi et al., 2017). Phytoremediation could be an eco-friendly technique for As remediation compared to chemical amendments, although there are limitations and drawbacks that require more research to exploit the benefit of phytoremediation in mitigating As in rice grains.

Bioremediation

Various microorganisms including bacteria, fungi and algae in the rhizosphere are resistant to As stress through different mechanisms like oxidation/complexation, solubilization, biosorption, methylation, sequestration etc. which can immobilize As in the soil solution. Successful inoculation of these microbes into the rhizosphere could alleviate As stress in contaminated paddy soil. The microbial immobilization and decontamination of As is achieved by: (i). oxidation and methylation of toxic As forms to less toxic forms, (ii). accumulation of As species at the extracellular surface of the microorganisms, (iii). formation of amorphous $\text{Fe}(\text{OH})_2$ on the cell surface and (iv). inhibition of the mRNA expression of As(III) transport pathways. Several As-resistant bacterial strains such as *Kocuria flava* AB402, *Bacillus vietnamensis* AB403, *Staphylococcus arlettae* (NBRIEAG-6), *Staphylococcus* sp. (NBRIEAG-6), and *Brevibacillus* sp. (NBRIEAG-6) have been identified with capacity to reduce As accumulation in rice crop. Some studies also reported arbuscular mycorrhizal fungi can decrease As translocation in rice tissues by suppressing the expression of As (III) transporters and ameliorate As stress to the rice plant by increasing antioxidant enzyme activity. The efficiency of bioremediation varies with the abundance of the microbial population, which is governed by several factors such as OC, pH, redox potential, soil nutrients, etc. (Jia et al., 2015). One study reported that among different soil factors, soil pH is the most limiting factor for microbial population abundance related to As transformation. The application of NO_3^- in flooded paddy soils substantially increased the As(III) oxidizing bacteria population and consequently reduced the bioavailable As (Zhang et al., 2017). Inoculation of Fe(II)/Mn(II) oxidizing bacteria immobilized As by promoting Fe-plaque formation in the root surface. In another study it was reported that inoculation of SO_4^{2-} -reducing bacteria and SO_4^{2-} fertilizer reduced the total As content in rice roots by about 23%. This was attributed to the immobilization of As(III) as As_2S_3 and FeS complex (Jia et al., 2015). Application of microbial inoculants could be an effective and environmentally friendly technique for mitigating As stress in rice. However, successful application of this practice may be limited by how the inoculated microbes will adapt to natural field conditions and compete with the indigenous microbial population.

Cultivars that exclude As or breeding of low As accumulating cultivars

Varietal differences in crop plants are associated with differences in translocation and uptake of As. For example, some rice cultivars have reduced As uptake because of their greater root porosity, radial oxygen loss and iron-plaque formation on the root surface (Suriyagoda et al., 2018b). Rice plants can also detoxify As through glutathione- or glutaredoxin-induced reduction of As(V) to As(III), the latter is transported out of the cell or sequestered into the vacuole (Suriyagoda et al., 2018a). Cultivation of rice varieties that accumulate small amounts of As could be an effective As mitigation option in contaminated paddy soils. A study showed that the total and inorganic As contents were larger in improved high yielding varieties than in local varieties. The varietal resistance of

rice plants to As is largely influenced by management practices and growing environment (Suriyagoda et al., 2018a). Therefore, remediation of As through varietal selection is a complex process and the performance is likely to vary in relation to growing conditions, soil types and cultural practices across the rice growing areas.

Conclusion and future research

Arsenic in agricultural soil is a great threat for food safety and human health. Thus, innovative mitigation strategies to diminish As accumulation in rice are urgently required to decrease these risks. Such solutions to reduce the As content in crop plant particularly in rice can be achieved by: exploiting genetic variations or the identification of existing rice cultivars that accumulate less inorganic As, different water management regimes and or the use of mineral nutrients as soil amendments to offset As uptake in grains. Limited resources have been directed towards mitigation strategies that minimize As accumulation in paddy rice using single techniques alone. Therefore, more research is needed on combined techniques, including organic and inorganic amendments, to immobilize As in paddy soils and decrease As in rice grains.

Abstract

The non-transition elements are the main group s- and p-block elements. The p-block elements that possess the hybrid characteristics of both metals and nonmetals are called metalloid elements. These elements exist naturally in the Earth's crust at varying concentrations; moreover they are used in many industrial processes and applications. In soil, they play key roles in several biochemical processes, which ultimately affect plant growth, food production and water quality. A review of the available data on the biogeochemical behavior of some non-transition metalloids (arsenic, barium, antimony, lead and selenium) in the soil system illustrates changes concerning their amounts and behavior (speciation, mobility or bioavailability) with implications for environmental health.

Key points

- The five non-transition elements (arsenic, barium, antimony, lead and selenium) have markedly different concentrations in soils, illustrating global scale pollution from anthropogenic activities.
- Soil pH, redox potential, microbial activities, mainly influence the speciation, behavior and phytoavailability of these elements in the soil ecosystem.
- A sustained effort is needed to minimize pollution risks, both by reducing vulnerability, use of (eco)toxic substances and the strengthening of health-environment regulations.

Introduction

The non-transition chemical elements are in the s- and p-block (depending upon the entry of last electrons in the s- or p-orbital) from Mendeleev's classification, including noble gasses. These elements include: (i) alkali metals such as potassium (K) and sodium (Na), (ii) alkaline earth metals such as magnesium (Mg) and strontium (Sr), (iii) chalcogens such as oxygen (O) and sulfur

(S), (iv) halogens such as chlorine (Cl) and bromine (Br), (v) actinoid series such as protactinium (Pa) and thorium (Th), and (vi) lanthanoid series such as praseodymium (Pr) and cerium (Ce), and (vii) metalloids such as arsenic (As) and silicon (Si). Metalloid elements are known to possess the characteristics of both metals and nonmetals; hybrid or intermediate properties. Owing to their hybrid or intermediate characteristics, it is not possible to classify them as either metals or non-metals. There is no commonly accepted definition of metalloid. Notwithstanding, the term 'metalloid' is consistently used in scientific literature.

Silicon (Si), tellurium (Te), boron (B), arsenic (As), germanium (Ge), and antimony (Sb) are currently known as the metalloids. In addition, selenium (Se), aluminum (Al), astatine (At), carbon (C), and polonium (Po) have been less frequently classified as metalloids. These 11 metalloids are present in a diagonal area of the p-block of a standard periodic table. Some elements such as beryllium (Be), bismuth (Bi), gallium (Ga), hydrogen (H) or zinc (Zn), occasionally classify as metalloids. Similarly, the p-block metals, and non-metals (nitrogen (N) and carbon) have also occasionally been referred to as metalloids as these elements have the potential to modify their characteristics by forming alloys with metals.

The characteristics of different metalloids vary from each other as well as from (non)metals. Overall, metalloids possess a metallic appearance. However, these elements are moderately good conductor of electricity and are brittle and shiny. The metalloids primarily refer to nonmetals because their chemical characteristics are very similar to nonmetals. Metalloids can form alloys with metals. However, the majority of their other physicochemical characteristics are between those of metals and non-metals. Depending on the method of classification, the number of elements characterized as metalloid varies: four, seven and 12 elements may be classified as metalloids. In this chapter, five non-transition metals and metalloids (arsenic, barium, antimony, lead and selenium) with contrasting properties, uses and behavior in the environment have been selected for further description (Kabata-Pendias, 2011). Table 1 and Fig. 1 respectively present the main characteristics of these non-transition elements and their positioning in the periodic table.

The five selected elements are used in numerous anthropogenic activities at the global scale, and of these lead, arsenic and antimony are associated with soil pollution. Table 2 gives the major producers of non-transition metals and metalloids with a major contribution by China (80000, 25000, 2400, and 1100 metric tons respectively of Sb, As, Pb and Se).

Arsenic

General information

Arsenic is a naturally occurring toxic metalloid and has become an element of prevailing concern (Natasha et al., 2021). It is the 20th most abundant element in the Earth's crust with 0.0001% crustal abundance (Shahid et al., 2018). The concentration of As in soil ranges $<1\text{--}250,000\text{ mg kg}^{-1}$, which varies with the nature of mineral sources. Arsenic and its compounds are classified among Group 1 carcinogens by various health- and environment-related organizations. Furthermore, it is categorized as the foremost among priority hazardous elements by the Agency for Toxic Substances and Disease Registry (ATSDR: Substance Priority List). To date, As contamination of the environment has been described widely, mostly in Asian and south Asian regions (Nagra et al., 2022). The major sources of arsenic released into the environment are geogenic (rock weathering, mineral decomposition and geothermal water). The anthropogenic sources include those from agriculture such as pesticides and fertilizers, from mining and smelting, and industrial activities. With the overexploitation of As-rich minerals, the discharge of As to farmland soil from irrigation is increasing. Large As concentrations also occur in the environment from the application of wastewaters and As-rich groundwater (Natasha et al., 2021).

Arsenic contamination of soil

Major As containing minerals are presented in Table 3. The natural or background As levels in the soil ranges from $0.5\text{ to }80\text{ mg kg}^{-1}$, with a mean of 10 mg kg^{-1} . But large soil As concentrations have been described in various areas worldwide (Table 4). Depending

2020	32,000	4400	153,000	2900

on parent rocks, arsenic exists in more than 200 natural minerals and arsenic concentration in igneous rocks may reach 100 mg kg^{-1} , in limestone (20 mg kg^{-1}), in Mn ores ($15,000 \text{ mg kg}^{-1}$), and in S ores (8000 mg kg^{-1}). The reductive dissolution of these minerals releases arsenic in natural waters and sediments (Natasha et al., 2021).

Arsenic bioavailability and speciation in soil

Arsenic bioavailability depends on dynamic and complex biogeochemical processes such as speciation, bioavailability, bioaccumulation, etc. These soil extractable or bioavailable arsenic fractions (less than the total in the soil) give insight into the mobility or phytoavailability of As in soil. It depends on the soil organic matter content, pH, redox potential (Eh), soil type, microbial functioning, and competing cations. The greater mobility and bioavailability of As in soil results in its large phyto-uptake. Arsenic in soil can exist in free ionic, exchangeable forms, adsorbed, precipitated or present as various minerals. Its bioavailability or potential toxicity is now well understood to depend on its chemical speciation rather than its overall concentrations. The species of As present in soil are listed in [Table 3](#).

Selenium

General information

Selenium is a common element in the Earth's crust (categorized 67th among the most abundant elements). Selenium distribution over the Earth's surface varies and ranges from near zero to 1250 mg kg⁻¹. Selenium is an essential element for living beings. It performs a dual role in the ecosystem: at large concentrations (and depending on speciation, and plant type) it can be phytotoxic, while at low-optimum concentrations, it is beneficial to plants (Natasha et al., 2018). Naturally, Se is released by forest fires,

volcanic eruptions, soil erosion and environmental oxidation reactions. Overall, much larger Se concentrations have been reported in sedimentary rocks (such as coal and shales) than in igneous rocks. Selenium occurs in coal deposits, for example in China, where the Se concentration in coal gangue varies from 0.06 to 17 mg kg^{-1} (Long et al., 2019). The sulphones of Fe, Co, and Ni, however, are detached by magmatic processes, and Se is emitted to the atmosphere. Selenium released to the atmosphere may contaminate soils by atmospheric deposition. For example, long-term Se deposition from rainwater has caused large Se concentrations in coastal areas of Ireland. About 50–65% of total Se global emissions are released by human activities.

Selenium contamination of soil

The major source of Se in soil is from weathering of rocks containing Se. The overall Se quantity occurring in rocks is about 40% of the total Se in soil. Natural Se concentrations in soil vary from 0.01 to 2 mg kg^{-1} , with a world mean of 0.4 mg kg^{-1} . Soils with a Se concentration of less than 0.5 mg kg^{-1} are said to be deficient in this element (Mirlean et al., 2017). The greatest concentrations of Se are found in shales (0.6 mg kg^{-1}) and volcanic rocks (0.35 mg kg^{-1}) from various areas of the world. However, Se concentrations may reach 8000 mg kg^{-1} in areas of its toxicity (Mora et al., 2015). Large Se concentrations in soil occur in North and South Dakota in the United States, and parts of China, Ireland, Wyoming, Venezuela and Colombia (Haug et al. 2007).

Selenium bioavailability and speciation in soil

Selenium occurs naturally in six isotopic forms that have atomic masses of 74, 76, 77, 78, 80 and 82, with ^{78}Se and ^{80}Se accounting for around 73.3% of the total mass. Selenium mostly occurs in ecosystems as sulfides (Table 3) or associated with other inorganic elements such as Cu, Ag, Ni or Pb. Some other minerals containing Se are: berzelianite, eucairite, umangite, penroseite, tiemannite, clausenthalite, klockmannite, palladseite, hakite, and selen-tellurium (Table 3). In soil, Se is present in insoluble forms, as Se^0 and Se^{2-} , but under aerobic conditions these are readily converted into their soluble forms i.e., selenate (SeO_4^{2-}) and selenite (SeO_3^{2-}).

The water-soluble Se fraction or Se in soil-pore water determines Se bioavailability in soil. Small concentrations of bioavailable Se in soil have been described in several studies (Natasha et al., 2018). Selenium mobility and bioavailability depend on the total Se concentration, and also on its oxidation state and speciation in soil. In general, three mechanisms govern Se bioavailability in soil i.e., oxidation vs. reduction, mineralization vs. immobilization, and volatilization. Soil redox conditions and pH, in particular, can affect Se speciation, and thereby its availability and phyto-uptake. In general, Se^0 and Se (II-) predominate in a reducing environment, whereas oxidizing conditions favor Se (IV) and Se (VI). The oxidized chemical forms (SeO_4^{2-} and SeO_3^{2-}) of Se have greater mobility than the reduced forms (Se^0 and Se^{2-}). The bioavailable forms of Se are Se(IV), Se (VI) and organic Se (Natasha et al., 2018) (Table 5).

Antimony

General information

Antimony does not have any biological function, and is categorized as a non-essential element (Pierart et al., 2015). Both natural (volcanic eruptions, rock weathering, wild fires, etc.) and human activities release it into the soil and water ecosystems (Natasha et al., 2019), which can lead to concentrations above the permissible limits. Consequently, it may be a harmful element to the environment. Antimony is the 62nd most abundant element in the Earth's crust (concentrations vary from to 0.2 mg kg^{-1}) and occurs in the Earth's crust as various ores (Table 3). It is ranked at 244th among hazardous contaminants by the ATSDR and the EPA ranked it at 114 in the US Environmental Protection Agency (USEPA) priority list of pollutants.

0.62	Netherlands	Grassland field	Supriatin et al. (2015)
0.53	Netherlands	Arable land	Supriatin et al. (2015)

Antimony contamination of soil

Table 6 shows that Sb concentration can vary widely in soil. The background level is 0.2 mg kg^{-1} , however, as a result of mining and smelting activities, and vehicle pollution, soil Sb concentrations might become many times greater (Pierart et al., 2015). In some areas, Sb concentration in soil exceeds the threshold level of 36 mg kg^{-1} . Antimony concentrations may reach 5045 mg kg^{-1} in the sediments and soil of contaminated areas.

Antimony bioavailability and speciation in soil

In soil, Sb occurs in different oxidation forms such as Sb (III) and Sb (V). However, under reducing conditions, Sb (III) is dominant, especially in paddy soils. The oxidative dissolution of antimony trisulfide (Sb_2S_3) in rocks naturally releases Sb in soil (Hu et al., 2017). Antimony may form complexes with different soil constituents such as Fe and Mn oxides. Numerous soil factors govern Sb mobility and phytoavailability such as its concentration, soil characteristics, redox conditions, and the competing ions. These factors can affect Sb speciation and hence its biogeochemical behavior in the soil-plant nexus. In particular, soil pH and redox conditions greatly affect soil-plant transfers of Sb in soil (Cui et al., 2015; Natasha et al., 2019).

Lead

General information

Lead (Pb) is a ubiquitous and versatile element, with a background concentration of 27 mg kg^{-1} (Kabata-Pendias, 2011; Natasha et al., 2020). It is the 36th most abundant element in the Earth's crust (with an overall value of 14 mg kg^{-1}). Lead is one of the major inorganic persistent global pollutants; its increased use in various industries and numerous other anthropogenic activities has enhanced its concentration in soil. With modern urbanization and industrialization, and with the recent past uses of Pb (material such as paints, petroleum, etc.), large quantities of Pb have been discharged into the soil (Fang et al., 2019). Exposure to lead is a health concern, especially for young children and pregnant women. Lead can affect almost every organ and system in your body. The nervous system is the main target for lead poisoning in children and adults. Exposure to lead can cause developmental effects in children, including but not limited to reduced IQ and attention span, hyperactivity, impaired growth, and learning disability.

Lead contamination of soil

In soil, large concentrations of lead are found around: roads as a result of emissions into the atmosphere from vehicles that used leaded gasoline for decades, buildings that used lead paint, toxic waste sites and other areas close to industrial sites such as the recycling of lead from car batteries (Natasha et al., 2020). Children and adults can be exposed to lead in soil through various leisure activities (gardening, eating contaminated fruits and vegetables or soil ingestion).

Interpreting soil lead results can be challenging as there is no single international threshold that defines acceptable levels of lead in soil. For example, the US-EPA (United States-Environment Protection Agency) sets a threshold for a child-occupied facility, such as a play area, of 0.4 mg g^{-1} of total lead. Lead generally forms stable complexes with soil components, therefore the observed environmental and toxic effects can be reduced (Zhang et al., 2019).

Lead bioavailability and speciation in soil

In general, Pb is distributed in different forms in soil for which the bioavailability differs significantly. Small concentrations only of soluble Pb are observed in soil because of its strong binding with organic matter and clay minerals (Kushwaha et al., 2018). Lead generally concentrates in the upper soil due to its low mobility and potential to form complexes with different soil particles.

It is now well-established that Pb speciation in soil mainly controls its geochemistry as well as phyto-uptake. Different chemical forms of lead have different adsorption and desorption potential that affect its behavior in the soil-plant nexus (Shahid et al., 2014). It is known that Pb exists in soil in different forms such as (i) Pb ions, (ii) complexed by HCO_3^- (bicarbonate), CO_3^{2-} (carbonate), SO_4^{2-} (sulfate) and Cl^- (chloride), or attached to fulvic, amino, and humic acids. In addition, Pb can also exist attached to organic matter, Fe-oxides, clay particles and biological materials.

According to Kushwaha et al. (2018), lead has no biological function and induces ecotoxicity in soil microflora and plants. Certain plants and microbes have evolved to develop detoxification mechanisms to counter the ecotoxic effect of lead and can be used for bioremediation of lead contaminated sites. These are mainly based on changes in chemical speciation. There are numerous options to reduce the bioavailability of lead in polluted soil including changes in soil pH, organic matter content, presence of various amendments, clay minerals and presence of organic colloids and iron oxides (Pourrut et al., 2011).

Barium

General information

Barium (Ba) is a silvery-white alkaline earth metal that occurs naturally in different compounds. It is the 16th most abundant element (0.04%) in Earth's crust, but it is not present in free ionic form because of its high chemical reactivity (Lu et al., 2019). It is also present naturally in surface water aquifers. Natural sources of Ba result from the weathering of minerals and rocks. Anthropogenically, Ba is mainly released by industrial activities. In the atmosphere, the residence time of Ba might be up to several days.

Barium contamination of soil

The major minerals of Ba are witherite (BaCO_3) and baryte (BaSO_4), often found in underground ore deposits (Krishna et al., 2020) (Table 3). Barium and its compounds have a variety of uses including as getter material in electronic tubes, rodenticides, color in paints and as an X-ray contrast medium. Barium is relatively abundant in the Earth's crust, with mean values ranging between 265 and $835 \text{ } \mu\text{g g}^{-1}$ dry weight (dw) depending on the soil type. Natural concentrations of Ba in soils range between 5 and $21 \text{ } \mu\text{g g}^{-1}$. In most soil systems, Ba is not a very mobile element due to the formation of water-insoluble salts and their partition into soils and sediments.

Barium bioavailability and speciation in soil

Witherite and baryte are both insoluble in water. i.e., 0.02 g L^{-1} (at 20°C) for BaCO_3 and 0.001 g L^{-1} (at 0°C) for barium sulfate. In minerals containing these elements, Ba largely substitutes Pb and Sr cations, but less so for the somewhat smaller Ca and K ions. Replacement for K shows a linked substitution to maintain charge balance. Barium occurs as a trace or minor element in potassium feldspar and mica in common igneous rocks, where it substitutes K. There is less substitution of Ca in amphiboles, apatite, calcite, plagioclase feldspar, and pyroxenes. Barium is usually found as baryte or as an organic complex in sedimentary rocks and hydrothermal deposits. The solubility, mobility and phytoavailability of Ba also vary under varying soil conditions such as pH and competing cations. Barium has been reported to precipitate in the presence of carbonate, sulfate, or chromate. For example, at $\text{pH} < 9.3$ with $\geq 2 \text{ mg L}^{-1}$ of SO_4 , Ba may precipitate as baryte (BaSO_4). Similarly, Ba precipitates as witherite (BaCO_3) with a large CO_3 concentration.

The water-soluble compounds of Ba are toxic and are often used as rodenticides. Sulfate is the stable form of sulfur in the Earth's crust and soil, therefore barium sulfate (BaSO_4), is fairly widespread, which explains the existence of trace quantities of baryte in many sedimentary rocks. Baryte has low solubility in oxidizing (sulfate-stable) conditions, but dissolves easily in reducing conditions with hydrogen sulfide (H_2S) (Lu et al., 2019). Barium solubility is known to be influenced by its species. Barium salts such as chloride, acetate, perchlorate, and nitrate are water soluble, whereas baryte (BaSO_4) is a very insoluble mineral (Krishna et al., 2020) whatever the solvent (water, acids, and bases) and is therefore has low (eco)toxicity (Menzie et al., 2008) (Fig. 2) (Tables 7 and 8).

Conclusions and perspectives

The five non-transition elements (arsenic, barium, antimony, lead and selenium) considered in this chapter show a wide range of different concentrations in the soils, illustrating global scale pollution by natural and anthropogenic activities such as metal(loid) mining. The main soil factors influencing the behavior of the five elements in soil-plant nexus are the soil pH, redox potential and biological activity, which govern their speciation and bioavailability in soils.

A sustained effort is needed to minimize further pollution risk induced by these non-transition elements, both by reducing vulnerability through remediation and mitigation strategies and by increasing law enforcement for minimizing the use of chemical fertilizers and pesticides on arable land. In 2022, with the reinforcement of environmental regulation and mobilization of public space for health, a reduction of chemicals released to the environment is being progressively observed in various sectors. For example, Registration, Evaluation, Authorization and Restriction of Chemicals (REACH) regulation in Europe aims to reduce the number of chemicals currently used. For agriculture, biological practices are being developed increasingly at the global scale to provide alternatives to pesticides. In addition, evaluating the potential of low-cost and eco-friendly amendments (such as green manure plants, biochar, etc.) combined with proper management of fertilizers and soil conditioners to govern the phyto-uptake of metal(loid)s should lead to practical and appropriate recommendations to farmers, gardeners and other relevant stakeholders.

Abstract

The relentless technological evolution of the world has resulted in the diffusion of new contaminants. The concurrent advances of analytical techniques have facilitated the recognition of actual and potential threats to human health and of the environment. Radon is a radioactive gas generated in rock and soil which is potentially mobile and can diffuse into the indoor and outdoor atmosphere. Lanthanides are elements classified as 'emerging contaminants' as their intense use in technological devices is resulting in their dispersion in the environment. Among the actinides, only thorium and uranium are widespread in nature.

Key points

- Technology demand for rare elements
- Dispersion of elements in soils
- Soil properties control their availability and mobility
- Improvement of analytical techniques
- Experimental gaps

Introduction

Lanthanides and actinides are elements that have gained recognition in recent decades for being identified as dangerous for the health of humans and of the environment. Radon, being a decay product of the actinide radium is also included here. Lanthanides, although they belong to the group of 'rare earth elements', are not rare in the lithosphere and are being intensively mined for applications in many so-called 'green' technologies. Actinides and radon radionuclides are mainly of natural origin as they derive from rocks, but the former have also been added to the environment through the exploitation of nuclear reactions. The consequent dispersion of these elements in the environment has been of increasing concern in recent years. This is particularly significant in an age when the green and ecological transition is regarded as vitally important.

The concern about these elements rises from a certain lack of knowledge about their reactivity, and consequently their fate, in the ecosystems. Little is known so far about the role of these elements in the soil–plant system and research is required to understand the possible threat deriving from the increased use of lanthanides and actinides.

Lanthanides

The lanthanides are a chemically uniform group of substances of Group IIIb in the Periodic Table that includes 15 metallic elements with atomic numbers 57–71 from lanthanum (La) through to lutetium (Lu), Fig. 1. Together with the elements scandium (Sc) and yttrium (Y) they constitute the group commonly known as the rare-earth elements (REE) or rare-earth metals.
